
I've always kind of been ahead of the game or ahead of the thinking in my own little field of entomology ... I think there will be individuals who can influence the direction of change. And I'd like to be among them, for whatever little part I might be able to play.

Ideas can act as forces of nature. They can change ecologies. They can reshape how we value and therefore how we treat nature. On behalf of biodiversity, biologists are making history: they are changing the course of events so that human history and natural history will unfurl to their liking. This encyclopedia attempts to inform, to raise awareness of both the science of biodiversity and the conscience of those who study it, revere it, and wish to see it preserved.

History suggests that two phenomena will continue: the biological complexity of the earth will continue to diminish, and biologists will continue to look for strategies that will compel us to care about what they care about and support their authority to speak for those entities. Biologists have attempted to raise our awareness of biodiversity: the complexity of real world organisms, species, and processes commingled with biologists' factual, political, emotional, ethical, aesthetic,

and spiritual values of the natural world, all combined to shape public perceptions, actions, and feelings. To become aware of it is to understand not only how biologists understand the riot of life and interconnections, but also to become aware of our own obligations to future evolutionary history.

International Organizations and Biodiversity

Margaret Goud Collins, International Institute for Applied Systems Analysis (IIASA), Laxenburg, Austria

Introduction

Biodiversity is an inherently international concern. Species distributions and the ecosystem services that they support are not defined by national boundaries. As a reflection of societal interests in those ecological benefits, international organizations have grown up to study, develop, regulate, and conserve the systems on which much of human well-being depends. These organizations, many of which were founded in response to the need for international cooperation in such areas as wildlife and wilderness conservation, scientific research, agriculture, forestry, water resources, aquatic resources, trade, pharmaceutical development, and economic development, have incorporated biodiversity concepts into their missions. Moreover, a number of issues are overlapping concerns of these different groups – invasive species control, for example, is where agriculture, forestry, and wildlife conservation meet up with trade.

As the interest in these issues has increased, and the complexity of, and threats to, global biological systems have become clearer, the diverse scientific communities studying science and policy related to biodiversity have developed stronger international ties. A central tenet of the new field of “sustainability science,” which focuses on the complex, dynamic interactions between nature and society, holds that “societies are complex adaptive systems, composed of individual agents who have their own priorities, and who value the macroscopic features of their societies differently. Resolving those competing perspectives is at the core of addressing sustainability” (Levin and Clark, 2010). The emphasis on social–ecological systems makes biodiversity a central element in the global network of institutions researching sustainability. However, the array of international organizations concerned with biodiversity and ecosystem services can themselves be viewed as a complex adaptive system, forming coalitions and adopting interests in response to scientific developments, economic forces, policy initiatives, and environmental changes.

International cooperation is crucial for the scientific investigation and conservation of biodiversity, and for the maintenance of the ecosystem services that biodiversity supports. International organizations foster and coordinate that cooperation, creating a complex network of governmental and nongovernmental international bodies to finance and conduct biodiversity research and conservation activities. Many of them participate in the provision of policy advice through national and international initiatives, undertaken in response to unprecedented ecosystem challenges stemming from economic development and climate change. Other organizations focus on the industries and public services that depend on biodiversity and ecosystems. Increasingly, the interests and mandates of these organizations overlap, requiring collaboration and cooperation among – and even within – the organizations, as it is not unusual for different bureaus within

the same association to address different sides of the biodiversity question.

UN Leadership on International Biodiversity Issues

Within this network of organizations, the United Nations (UN) serves as a hub, both for intergovernmental cooperation and for partnerships with governments, nongovernmental organizations (NGOs), and industry. In each of the subject areas discussed here, UN agencies are crucial for both coordinating and funding international activities. Biodiversity-related issues have been among UN concerns since its earliest days, and the role of the United Nations Educational, Scientific and Cultural Organization (UNESCO) in the creation of the International Union for the Conservation of Nature (IUCN) offers one of the earliest examples of UN promotion of international cooperation through NGO partnerships. Since its creation in 1972, the United Nations Environment Programme (UNEP) has been at the heart of the UN environmental activities, and the Global Environment Facility (GEF) was established in 1991 to provide coordinated funding for global environmental issues (GEF Website, 2011). However, environmental concerns are woven into activities throughout the organization. On the UNEP website, a diagram of the “environmental DNA” of the UN system lists 44 UN entities that play explicit roles in environmental issues (UNEP Website, 2011), and most of these include biodiversity and ecosystems among their priorities. The ubiquity of biodiversity interests was summarized in a report prepared for the International Year of Biodiversity (IYB) in 2010 (UN Environment Management Group, 2010). The recognition that the 2010 biodiversity conservation targets had not been met, and the importance of the challenges, led the UN to designate 2011–2020 as the International Decade on Biodiversity, in order to highlight the urgency of achieving the next set of decadal goals (CBD Website, 2011).

The most significant global assessment of biodiversity and ecosystem services to date, the Millennium Ecosystem Assessment (MA), was a joint initiative of four intergovernmental organizations and NGOs – UNEP, UNESCO, World Bank, and the World Resources Institute (WRI) – with support from a total of seven UN entities. It enlisted the skills of more than 1360 experts worldwide, and their findings provide a framework for understanding the importance of biodiversity and ecosystems for human well-being, as well as a record of the state and transformations in ecosystems around the world (Reid *et al.*, 2005). The MA sparked a renewed recognition of the pervasiveness and increasing urgency of biodiversity and ecosystem concerns, as a consequence of which the UN General Assembly approved in 2010 the creation of an Intergovernmental Platform for Biodiversity and Ecosystem Services (IPBES). The IPBES will create a new intergovernmental institution, comparable to the Intergovernmental Program on

Climate Change (IPCC), to provide a mechanism to contribute to global policy deliberations through regular assessments of biodiversity and ecosystem services. These assessments will be performed by the global academic, governmental, industry, and NGO communities with interests in biodiversity (IPBES Website, 2011). The new institution may, in turn, help introduce more coherence and consistency into the conservation and development strategies of governments, industries, and NGOs, if IPBES is able to lead to common, and improved, understandings of the baseline conditions, possible future scenarios, and complexities of ecosystem change.

This article attempts both to catalog institutions and their missions, and to capture the dynamism of their interactions and activities. It outlines the framework of international organizations concerned with biodiversity issues in a variety of contexts, with sections focusing on such topics as biodiversity conservation, biodiversity research, collecting and archiving biodiversity data, and the confluence of biodiversity issues with economic activities such as agriculture, fisheries, forestry, and trade.

International Organizations and Biodiversity Conservation

Wildlife and habitat conservation were the primary concerns of the first international conservation organizations, which served as the kernel of what became the global environmental movement of the late twentieth century. Early conservation organizations, such as the Wildlife Conservation Society (founded in 1895 as the New York Zoological Society) and Flora and Fauna International (founded in 1903 in the United Kingdom as the Society for the Preservation of the Wild Fauna of the Empire), developed early conservation norms. They were then joined by new international organizations as the scope of conservationists' interests broadened. The new and evolving organizations began to apply the groups' lessons and approaches worldwide.

Intergovernmental conservation efforts were among the earliest activities of the UN, principally through UNESCO. Shortly after its establishment in 1945, UNESCO partnered with governments and national organizations to launch the IUCN, initiating a tradition of partnerships between international governmental organizations and NGOs to accomplish conservation ends. The initial focus of IUCN in the 1950s was on endangered species and protected areas, and in 1963 the organization established the Red List of Threatened Species, aimed at drawing attention to the magnitude and importance of threats to biodiversity worldwide (IUCN Website, 2011; International Union for the Protection of Nature, 1948).

IUCN was joined in succeeding decades by an array of international organizations focused on conservation of threatened species and the ecosystems in which they lived. The World Wildlife Fund (WWF) was founded in 1961 to advocate for the protection of wildlife and wild places around the world. Their campaigns used "flagship species," such as the iconic panda of their logo, to raise awareness and stimulate action and funding for their global activities and advocacy (WWF Website, 2011). In the 1980s, the Nature Conservancy

went international with its successful US model of purchasing and managing ecologically valuable properties, joining WWF and Conservation International (CI) in pioneering "debt-for-nature" swaps in Latin America and elsewhere (The Nature Conservancy Website, 2011). CI was founded in 1987, and their approach emphasizes partnerships with businesses and governments to provide resources and develop policies for the conservation of biodiversity and natural habitats in concert with economic development (Conservation International Website, 2011). CI has prioritized the preservation of areas they have designated as Biodiversity Hotspots, defined as places with very high numbers of endemic species in immediate need of conservation action in order to survive (CI Website, 2011a). Other international NGOs focus their efforts on narrower swaths of the biodiversity spectrum, such as BirdLife International, Botanic Gardens Conservation International, and the World Association of Zoos and Aquariums. Some concentrate on regional biodiversity conservation concerns, such as the Africa Wildlife Foundation, founded in 1961.

Biodiversity and conservation were among the central concerns in the explosion of environmental interest and activism in the 1970s, and intergovernmental conservation activities saw a concomitant growth. Since 1971, UNESCO has sponsored the Man and the Biosphere (MAB) Program with an emphasis on integrating conservation with human activity, overseeing the creation of a World Network of Biosphere Reserves (WNBR) as a testbed for research into innovative approaches to sustainable relationships between human societies and natural systems. Since the approval of the first WNBR site in 1978, the network has grown to encompass 580 sites in 114 countries. The mandate of the program has evolved from conservation and managed resource use to incorporate research into mitigation and adaptation to climate change in a broad range of ecosystems.

The focus on conservation of wildlife and habitat was a central theme of the UN Conference on Human Environment in Stockholm in 1972, and of the UNEP, which was founded shortly afterward. UNEP emerged as a key player in international biodiversity research and conservation. The 1970s also saw the negotiation and adoption of international legal instruments for biodiversity protection, including the following:

- The Convention on Wetlands of International Importance, or the Ramsar Convention, provided a framework for the conservation and wise use of wetlands, particularly ones of importance for waterfowl; the list of Ramsar sites in 2011 numbered 1952 (Ramsar Website, 2011).
- The Convention Concerning the Protection of the World Cultural and Natural Heritage, or the World Heritage Convention, oversees the preservation of sites that are valuable to the entire world citizenry, whether natural or cultural. Adopted and administered by UNESCO, the list in 2011 contained 936 properties (World Heritage Convention Website, 2011).
- The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) entered into force in 1975, to monitor and regulate the interstate transport of wild animals and plants to ensure sustainability.

- The Convention on Migratory Species of Wild Animals (CMS) was signed in 1979 to regulate the conservation and management of migratory species. Administered by UNEP, CMS develops and promotes regional and global agreements related to specific migratory species, among which are bats, cetaceans, and gorillas.

These piecemeal tactics for protection highlighted the need for a global approach to the protection of species, an issue that was galvanized after the 1987 National Academy of Sciences Conference on BioDiversity highlighted the urgency of a wise policy of conservation and development, and Gro Harlem Brundtland's 1987 report *Our Common Future* called for a Species Convention. UNEP took the lead in drafting what became the Convention on Biological Diversity (CBD). The convention was approved at the 1992 UN Conference on Environment and Development – the Earth Summit – as was the UN Framework Convention on Climate Change (UNFCCC). The three goals of the convention are the conservation of biodiversity, the sustainable use of biodiversity components, and the fair sharing of the benefits of genetic resources (Juma and Henne, 1997). The CBD obligates signatories to develop national plans for biodiversity conservation, and the CBD organization develops programs of work to achieve its conservation goals.

As the understanding of the complexity of environmental systems and their interactions with human society has grown, the agendas of all of these organizations have evolved. All have contributed to the MA and have incorporated its core findings regarding the linkages between ecosystems and human well-being. Each organization maintains a distinct strategy and focus, but their missions and work programs have developed to encompass the importance of ecosystems for the preservation of species, the importance of understanding and harnessing broad economic and political forces for conservation, and the critical role of raising global public awareness of the importance of biodiversity and ecosystem services.

International Organizations and Scientific Research Cooperation in Biodiversity

The concept of biodiversity arose from the scientific community, whose members have a long history of international cooperation in studying and promoting the conservation of natural systems. Scientific research is woven into the activities and strategies of every one of the international governmental and nongovernmental conservation organizations discussed earlier. The scientific community participates in and is supported by the conservation community, in a complex and evolving system of interactions.

The earliest international organizations dedicated to promoting international cooperation in biological research were the International Union of Biological Sciences (IUBS), founded in 1919, and the International Union of Microbiological Sciences (IUMS), founded in 1927, the memberships of which were national scientific societies. IUBS was among the founding members of the International Council for Science (ICSU) in 1931, formed as an umbrella organization to promote international cooperation in science, and IUMS joined in 1982.

With its wide-ranging scientific overview, ICSU has promoted interdisciplinary, integrated scientific approaches to global environmental issues, including a number of programs that have made significant contributions to international cooperation in biodiversity research. These include the Scientific Committee on Problems of the Environment (SCOPE; founded in 1969), the Scientific Committee on Ocean Research (SCOR; founded in 1957), the Program on Ecosystem Change and Society (PECS; founded in 2008), and the four programs devoted to global change research: the World Climate Research Program (WCRP; created in 1980), the International Geosphere–Biosphere Program (IGBP; created in 1986), the International Human Dimensions Programme on Global Environmental Change (IHDP; created 1996), and the International Programme of Biodiversity Science (DIVERSITAS; established in 1991 by IUBS, UNESCO, and SCOPE, which were joined by ICSU and IUMS in 1996). In addition to the international coordinating function provided by the ICSU family, some scientific professional societies are international in scope. Most notably, the Society for Conservation Biology has a broad international membership of scientists, social scientists, economists, and professionals such as lawyers and teachers interested in science and policy of biodiversity and ecosystems.

These nongovernmental, scientific coordinating organizations have played a crucial role in defining international scientific priorities, promoting international research collaboration, and providing input to national and international policy deliberations. ICSU is often called upon to represent the international scientific community in UN fora and has served as a partner to UN agencies in achieving their scientific goals. For example, in preparation for the UN Commission on Sustainable Development's "Rio + 20" conference in June 2012, ICSU organized regional science and technology workshops, and participated in intergovernmental preparatory meetings. ICSU's programs are generally organized with input from intergovernmental organizations such as UNEP and UNESCO, and thus reflect global governmental priorities and needs for input.

Two of the ICSU initiatives have an explicit biodiversity focus: DIVERSITAS and PECS. DIVERSITAS was created to integrate the broad range of biological sciences needed to understand observed loss and change in global biodiversity, and its scope evolved in concert with the insights enunciated in the MA to incorporate more policy relevant aspects of biodiversity and ecosystem change. The organization provides an umbrella for international research cooperation on topics from evolution to biodiversity data to sustainability, and co-operates in the biodiversity and ecosystem aspects of the other ICSU programs in the Earth System Science Partnership (ESSP), particularly IGBP and IHDP. DIVERSITAS is also an active partner with intergovernmental organizations, providing scientific support to the CBD and co-chairing the Biodiversity Observation Network of the intergovernmental Group on Earth Observations (GEO BON). DIVERSITAS was a leader in advocating the scientific communities' views as the proposal for IPBES was developed, and represented ICSU at the UN-sponsored negotiations for the establishment of the organization in 2011–2012.

The more recent ICSU initiative related to biodiversity and ecosystems, PECS, aims to complement the ESSP programs by

developing an international program of work on social-ecological systems, with particular focus on assessing the effects of policies and practices on the resilience of critical ecosystem services. Along with DIVERSITAS, it will provide scientific input to the proposed IPBES (ICSU Website, 2011a).

Other international organizations conduct research on biodiversity and ecosystem services, many serving as hubs of regional and global research networks. Among the organizations with significant biodiversity-related activities are the following:

- The WRI, a policy research institute addressing global resource and environmental issues founded in Washington, DC, in 1982, was a key organizer of both the 1995 Global Biodiversity Assessment and the MA. WRI collaborates with UN agencies to produce the World Resources Report biannually.
- The International Institute for Applied Systems Analysis (IIASA), an international nongovernmental institute, founded in 1972 near Vienna, Austria, conducts systems analysis research on global problems, including evolution, land use, and ecosystem services.
- The Inter-American Institute for Global Change Research (IAI) and the Asia-Pacific Network for Global Change Research (APN) are intergovernmental organizations serving as hubs for networks of research institutions working on global change issues in the Americas and the Asia-Pacific region, respectively. Both organizations promote science that cannot be conducted by any one country alone through research grants to international teams, scientific meetings, and capacity building. Biodiversity and ecosystems are key elements of their agendas.

International Organizations and Biodiversity Data

The conduct of research, the development of conservation priorities, and the understanding of changes in ecosystems are all dependent on the analysis of reliable global data sets. The cataloging and preserving of accurate records of life on Earth presents particular challenges. The traditional repositories of biodiversity data are local institutions such as natural history museums and academic collections. They rely on international standards for the names of plants and animals that have long been overseen by the International Association for Plant Taxonomy and International Commission on Zoological Nomenclature. However, recent decades have witnessed an explosion of both remotely sensed data that offer a global context for ecosystem understanding and genetic data that offer a new understanding of the molecular basis for biological diversity. In addition, new information technologies provide previously unimaginable opportunities for global access to biodiversity data. These developments have led to an array of international organizations devoted to collecting and maintaining these data, and to making them available for use by the global science and policy communities.

The Global Biodiversity Information Facility (GBIF), established in 2001 as an intergovernmental initiative to encourage free and open access to biodiversity data via the

Internet, had as of 2011 built a global network of 57 countries and 47 organizations. GBIF promotes and facilitates the mobilization, access, discovery, and use of information about the occurrence of organisms over time and across the planet (GBIF Website, 2011). The Consortium for the Barcode of Life (CBOL) is an international initiative established in 2004 devoted to developing DNA barcoding as a global standard for the identification of species. Its International Barcode of Life (iBOL) project is coordinating a 26-nation research alliance to construct a global DNA barcode reference library for that purpose. The Encyclopedia of Life (EOL) is a global partnership, begun in 2007, with a goal of compiling an online, dynamic catalog of every species on Earth. The EOL partnership included 181 content partners as of 2011, making it a link to an array of biodiversity databases on organisms from microbes to whales (EOL Website, 2011).

The UNEP World Conservation Monitoring Centre (UNEP-WCMC) is a collaboration between UNEP and the UK-based charity WCMC that supports international biodiversity conservation initiatives by compiling, storing, and analyzing biodiversity data on matters of relevance to international conventions (such as CBD and CITES), businesses (through its Proteus partnership), and conservation and research organizations. Databases supported by UNEP-WCMC include the World Database on Protected Areas; the UNEP-WCMC Species databases on organisms of conservation importance, including those protected by multilateral environmental agreements; and the CITES database of trade in protected species (UNEP-WCMC Website, 2011).

GEO BON is the biodiversity component of the Global Earth Observation System of Systems (GEOSS). It encompasses a partnership of some 100 governmental organizations and NGOs and is chaired by DIVERSITAS, NASA, and the EU Biodiversity Observation Network (E-BONE). The GEO BON goal is to collect and make accessible a comprehensive collection of *in situ* and remotely sensed biodiversity observations, accompanied by tools for analysis that enable decision making in support of conservation and management of resources (GEO Website, 2011).

Among the best known independent databases is the IUCN Red List of Threatened Species. From its beginnings in 1963, the Red List has grown into “the world’s most comprehensive inventory of the global conservation status of plant and animal species,” utilizing resources from museums, conservation organizations, and academic institutions to provide data on approximately 45,000 species, including both threatened and nonthreatened organisms. Partners such as BirdLife International, which connects avian conservation organizations in more than 100 countries, coordinate specific elements of the database. With a new focus on scientific rigor and transparency in the 1990s, the Red List has evolved into a valuable tool for conservation strategies (IUCN Website, 2013).

International Organizations and Biodiversity for Agriculture and Forestry

Humanitarian, commercial, and conservation concerns converge in global cooperation related to agriculture and forestry. Traditional efforts to develop seeds and efficient production

methods to aid in the fight against hunger or increase the economic viability of agricultural enterprise have been influenced by the recognition that valuable genetic resources were being lost in the process of modernization. Forest management has developed beyond the concept of maximum sustained yield to incorporate an approach that can maximize the value of a broader range of ecosystem services provided by forest ecosystems. Expanded global economic integration has accelerated the introduction of new species into far-flung corners of the globe, some on purpose, others accidentally. Some of these invaders have been so successful that their proliferation threatens the existence of the ecosystems that they have colonized, endangering both economic and cultural services that the ecosystems provide. The global intertwining of ecosystems, ecosystem services, and ecosystem threats has generated a complex international institutional framework aimed at understanding and regulating these ecosystem-dependent economic activities to increase and balance the societal benefits and costs.

Agriculture and Biodiversity

The boom in international cooperation in agricultural research dates back to the 1950s and 1960s, when private foundations and the World Bank began funding the development of “miracle grains” in specialized research institutes around the world. These collaborations were integrated and institutionalized with the creation of the Consultative Group on International Agricultural Research (CGIAR) in 1971, funded by a consortium of donor countries, foundations, and multilateral organizations (CGIAR Website, 2011). During that same period, the erosion of plant genetic resources was attracting the attention of the UN Food and Agriculture Organization (FAO) and was widely discussed at the 1972 UN Conference on the Human Environment. Shortly thereafter, the IUCN added *Threatened Plant Species* to its Red List system, focusing on plants that fell outside the interests of the FAO (Maunder, 2001), and the preservation of plant and animal genetic resources, particularly in the context of agriculture, took a central place on the agendas of international conservation, research, and development organizations.

The FAO began in the 1970s to integrate biodiversity and sustainability into its structure and core activities. The FAO Commission on Genetic Resources for Food and Agriculture (CGRFA), established in 1983, has collaborated with CBD and CGIAR in assessments of plant, animal, and forest genetic resources, and on initiatives for the conservation and sustainable use of soil biodiversity. CGRFA also oversaw negotiations for the International Treaty on Plant Genetic Resources for Food and Agriculture, adopted in 2001 to facilitate access and share benefits, and FAO helps set standards and global frameworks for collection, storage, preservation, and sustainable use of genetic resources.

International efforts to expand seed bank collections as a hedge against species loss have been spearheaded by botanical gardens and the Global Crop Diversity Trust (GCDDT), which was jointly established by FAO and CGIAR/Biodiversity International. The Trust has collaborated with the Government of Norway to establish the Svalbard Global Seed Vault as

a backup conservator of the world’s gene bank collections against strife and natural disaster. The Millennium Seed Bank, sponsored and hosted by Kew Royal Botanic Gardens, works with a network of international partners to conserve wild plant diversity.

As of 2011, the CGIAR comprised a consortium of 15 research centers, and their research agenda had expanded beyond crop genetic improvement to include sustainable pest management and agricultural technologies, as well as research on the efficacy of proposed agricultural policies. In particular, Biodiversity International (formerly International Plant Genetic Resources Institute), located in Rome, focuses on how agricultural biodiversity can be used to improve nutrition and make agriculture more sustainable both economically and environmentally, and the International Food Policy Research Institute (IFPRI) in Washington researches policies and practices that can improve the sustainability of food production. A number of the centers are conducting research in agricultural and agroforestry landscapes, incorporating biodiversity as an element of research programs (CGIAR Website, 2011a).

In an effort to assess the challenges facing the global agricultural enterprise, including its relationship to ecosystems, agricultural livelihoods, agricultural knowledge, and food policies, seven UN agencies launched the International Assessment of Agricultural Knowledge, Science and Technology for Development (IAASTD). The 3-year effort culminated in a 2008 synthesis report that analyzed issues and global scenarios for agricultural goals related to reducing hunger, improving health and rural livelihoods, and fostering environmental and social sustainability. Five subglobal assessments captured the regional differences in agricultural scenarios (IAASTD Website, 2011).

Conservation organizations and the international conservation science community are also exploring the connections between agriculture and biodiversity conservation. The MA observed a dichotomy between agricultural research and conservation biology, in which, for example, research on related species and landscapes proceeded on parallel tracks and without significant communication. International organizations are involved in efforts to bridge that divide. The DIVERSITAS agroBIODIVERSITY program fosters international research cooperation “to address the trade-offs between food production, biodiversity conservation, ecosystem services, and human well-being in agricultural landscapes” (Jackson *et al.*, 2005). International conservation organizations have also added sustainable agriculture to their activities, advocating alternatives to the slash-and-burn approach that is so destructive of forest ecosystems. In these efforts, conservation organizations are finding institutional partners from the business community. For example, IUCN joined with the World Business Council for Sustainable Development to produce a 2008 report calling attention to challenges related to agriculture and food security, WWF works with partners from local producers to international markets to promote practices and policies for sustainability (World Wildlife Fund Website, 2011), and the Conservation International Center for Environmental Leadership in Business negotiates agreements with international producers such as Starbucks to promote sustainable agricultural practices (CI Website, 2013).

Forestry and Biodiversity

As discussed in the previous section, much of the work by FAO and CGIAR on agriculture and biodiversity has elements related to forestry and forest biodiversity. However, in the context of the UNFCCC, a new international organization has become a major player in forest conservation since 2009. The UN Program for Reducing Emissions from Deforestation and Forest Degradation (UN-REDD) is an intergovernmental agreement, jointly executed by FAO, UNDP, and UNEP, to create financial value for the carbon stored in forests, offering incentives for developing countries to reduce emissions from forested lands and invest in low-carbon paths to sustainable development, including biodiversity conservation. UN-REDD works in close coordination with the World Bank's Forest Carbon Partnership Facility (FCPF), which assists tropical and subtropical forest countries to develop REDD strategies.

Implementation of the REDD program, with its emphasis on sustainability and improved livelihoods, is important for both conservation and the forestry industry. International conservation organizations, such as WWF, IUCN, CI, and the Nature Conservancy, as well as the intergovernmental International Tropical Timber Organization (ITTO), have longstanding programs of research, field work, and policy development related to both forestry and climate, and they are active both in UN-REDD and in advising national REDD programs. Other multilateral development banks, such as the Asian Development Bank and the Inter-American Development Bank, are developing strategies to take advantage of emerging financial incentives for forest conservation under REDD.

Accelerating international trade is leading to increasing risk of introducing destructive invasive species, which can cause severe damage to forest ecosystems and ecosystem services. These invasive organisms range from disease-causing microbes to weeds to destructive insects to imported game animals, and can lead to significant economic harm. For that reason, the international trade negotiators incorporated the right to preserve plant, animal, and human health into the rules governing international trade. The Sanitary and Phytosanitary Agreement in the General Agreement on Tariffs and Trade (GATT) was incorporated into the structure of the World Trade Organization (WTO), giving the WTO a voice in a key area of biodiversity and ecosystem conservation.

International Organizations and Aquatic Biodiversity

Marine and freshwater biodiversity have a long history of international study and regulation, and a concomitantly broad array of organizations with interests in aquatic biodiversity. The reasons are manifold: much of the marine realm is located outside national boundaries; many marine and freshwater organisms are mobile, traveling readily between and among different national and international regimes; aquatic biodiversity provides an important source of food and resources, and the societies and industries that rely on those resources have long recognized the need to protect them from excessive exploitation and damage from pollution. More recently, new imperatives for understanding and protecting marine

biodiversity have arisen because of increased understanding of the role of marine microorganisms in critical biogeochemical processes that regulate atmospheric composition and global climate, and the new and poorly understood biological effects of global ocean acidification caused by the ocean's absorption of anthropogenic greenhouse gases.

UN agencies are central to marine biodiversity conservation. The UN Convention on Law of the Sea (UNCLOS) includes a Convention on Fishing and Conservation of Living Resources of the High Seas, which is one among dozens of global and regional instruments of international law designed to govern the exploitation of marine life and protect it from damage through pollution or overexploitation. There are specific agreements on whales, seals, marine mammals, sea turtles, cetaceans, sea birds, Antarctic marine life, highly migratory species, and straddling or anadromous stocks, in addition to the elements of CITES, CBD, and other treaties that apply to marine environments (*International Fisheries Agreements*, 2008). Some are executed by distinct international organizations such as the International Whaling Commission, set up by the International Convention for the Regulation of Whaling in 1946, which governs the conduct of whaling, maintains whale databases, and funds and publishes whale and whaling research. Another example is the Commission for the Conservation of Antarctic Marine Living Resources, which enforces the Convention on Antarctic Marine Living Resources. Other elements of the UN responsibility for marine life reside in UNDP, UNEP, FAO, CBD, and UNCLOS. Because of the UN's broadly distributed responsibilities for marine resources, a number of coordinating mechanisms have been established. In 1969, the Joint Group of Experts on the Scientific Aspects of Marine Environment Protection (GESAMP) was created to provide scientific guidance on marine issues to any of the nine sponsoring UN agencies, utilizing working groups of international experts; GESAMP prepared a report on marine biodiversity in 1997 (*GESAMP*, 1997) and has regularly considered biodiversity-related issues. To coordinate UN oversight of marine biodiversity, a task force on Marine Biodiversity Beyond National Jurisdiction was set up by the UN-Oceans interagency organization in 2005. The task force is jointly led by the UNCLOS and CBD.

Marine governance depends on data, and international databases are supported by a network of intergovernmental and independent international organizations. UNESCO's Intergovernmental Oceanographic Commission (IOC) manages the Global Ocean Observing System, which supports a number of remotely sensed databases related to marine biodiversity. Integrated fisheries databases are maintained by the Fishery Resources Monitoring System (FIRMS) in order to provide high-quality information for monitoring and managing fishery marine resources (*FIRMS Website*, 2011). FIRMS integrates data collected from a network of intergovernmental organizations such as the intergovernmental International Council for the Exploration of the Sea (ICES), which conducts research, maintains marine databases, and provides scientific advice to governments and international regulatory bodies related to the North Atlantic, and the Southeast Asian Fisheries Development Center, which promotes sustainable fisheries development in Southeast Asia, as well as conducting research and training.

International conservation and research organizations are likewise active in marine biodiversity issues. IUCN is leading an international consortium of organizations in a Global Ocean Biodiversity Initiative (GOBI), building on the Census of Marine Life assessment to compile a database to CBD standards that can be used as a scientific basis for conserving marine biodiversity (GOBI Website, 2011). The Nature Conservancy sponsors projects around the world aimed at protecting marine resources while also developing sustainable human communities adjacent to the sea. WWF has a Global Marine Program focusing on ecosystem-based management, “smart fishing,” and protection of priority areas of great biological diversity. WWF is also sponsoring roundtables with aquaculture stakeholders to develop standards for sustainable aquaculture.

Biodiversity and International Business Strategies

Biodiversity and ecosystem services are important to global economies. For that reason, international organizations engage in research to understand the role of ecosystems’ “natural capital” in economics and work with businesses to ensure that economic development is compatible with the preservation of biodiversity.

The Economics of Ecosystems and Biodiversity (TEEB) is an intergovernmental initiative coordinated by UNEP to evaluate ecosystem services, including costs of biodiversity loss and strategies for governments and businesses to minimize those losses (TEEB Website, 2013).

The potential to use biodiversity as a source for the development of new commercial products, particularly pharmaceuticals and biofuels, has caused conflict between poor countries with rich biodiversity resources and the companies and nations that have the intellectual and financial resources to commercialize them. International organizations play a significant role in developing equitable solutions to those disputes. Moreover, conflicts of this sort combine with information campaigns by environmental advocates to raise public awareness of the importance of biodiversity and the negative effects that global development and trade can have. This awareness plays out in consumer preferences that create incentives for businesses to make their operations more sustainable.

International organizations have developed programs designed to assist enterprises with their sustainability strategies. These programs vary depending on the scale of the business, ranging from households looking to raise their incomes beyond subsistence levels through collection of organic, wild collected products, to global exporters of agricultural products that require a “green” certification for their biodiversity-friendly products and production methods. The International Trade Center (ITC), a joint program of the UN and the World Bank, works with small and medium-sized enterprises to comply with green certification schemes, both to ensure sustainable supply of “biodiversity products” or organic crops and to improve access to markets for small producers. They offer information, advisory services, and training for producers in developing countries (UN-ITC, International Trade Center Website 2011).

The Forest Stewardship Council (FSC) is one example of an international organization that uses a certification program to

promote responsible management of the world’s biodiversity resources. The FSC develops standards and conducts inspections to assure that forest products are being harvested with due respect to both forest-dependent communities and biodiversity (FSC Website, 2011). To certify the standards of the FSC, it has collaborated with environmental organizations such as WWF, which endorses the FSC on its website. It is also a member of the ISEAL Alliance, the global association for social and environmental standards (ISEAL Alliance Website, 2011). Other biodiversity-related accrediting organizations that are members of ISEAL include the International Federation of Organic Agriculture Movements, International Organic Accreditation Service, the Marine Aquarium Council, the Marine Stewardship Council for sustainable wild seafood, the Rainforest Alliance/Sustainable Agriculture Network, the Roundtable on Sustainable Biofuels, and Union for Ethical Bio Trade for ingredients from native biodiversity.

Civil Society and Biodiversity

A number of international organizations doing research related to international economic development are engaged in work related to biodiversity conservation as an element of sustainable development. Likewise, relief organizations are recognizing that damage to ecosystem services is a consequence of relief activities during humanitarian crises, and mitigating those damages can be a valuable addition to planning. The convergence in interests and activities between these organizations, such as the International Institute for Environment and Development in London, the Center for Global Development in Washington, the Red Cross, and the international science and conservation organizations discussed earlier (*see* International Organizations and Biodiversity Conservation), demonstrates the breadth of the biodiversity agenda and its importance to all elements of human well-being.

Destruction of ecosystems and threats to biodiversity are endemic to human activity, and the international conservation community has recognized that humanitarian crises such as natural disasters, military conflicts, and the refugee emergencies that result can be compounded by the environmental consequences of the international interventions meant to relieve human suffering. In consequence, international conservation organizations have formed Stewardship Council partnerships to help in aid and recovery planning. For example, the UN High Commissioner for Refugees (UNHCR) has worked with international partners to develop sound environmental practices in establishing and operating refugee camps, both to mitigate degradation and to avoid conflicts over resources (UNHCR Website, 2011). UNHCR worked with CARE International, and relief workers in the field, to develop a toolkit to help field workers and managers make rapid environmental assessments to help minimize adverse environmental impacts and conflicts with surrounding communities (UNHCR, 2009). Likewise, WWF has worked with the Red Cross to develop guidelines for environmentally sustainable reconstruction efforts, a partnership that developed in the aftermath of the Indian Ocean tsunami in 2004 (WWF 2011a).

Conclusion

This article offers a framework for understanding how international organizations contribute to the understanding and handling of the questions of biodiversity and human well-being. Although the author has made efforts to include the most important of the groups working in this sphere, the discussion cannot be considered exhaustive and, in addition, is in a constant state of flux, as organizations form, disperse, and change names or focus. Some important organizations and initiatives have undoubtedly been omitted.

Justice, Equity and Biodiversity

Kai MA Chan and Terre Satterfield, University of British Columbia, Vancouver, BC, Canada

© 2013 Elsevier Inc. All rights reserved.

Glossary

Ecosystem services Conditions and processes through which natural ecosystems, and the biodiversity they comprise, sustain and fulfill human life. Examples include provision of clean water, maintenance of livable climates (carbon sequestration), pollination of crops and native vegetation, and cultural, spiritual, and intellectual inspiration.

Environmental justice Balanced distribution of costs and benefits among stakeholders in the design and implementation of environmental policies and projects.

Equity State, quality, or ideal of being just, impartial, and fair.

Justice The appropriate treatment of others; fairness in actions, rules, and outcomes.

Livelihood Possession of income and access to resources sufficient to meet basic life needs.

Restitution Act of restoring to the rightful owner something that has been taken away, lost, or surrendered; the act of compensating for loss, damage, or injury.

Introduction

The struggle to sustain biodiversity is a struggle for justice and equity, a struggle to treat others fairly where the others include not only existing people but also future generations and nonhuman organisms. But in an urgency to protect biodiversity, the interests of existing people – especially those who are physically proximate to protected areas – have often been transgressed. To guard against human injustices while also advancing the fair treatment of nonhuman organisms and future people, we need a coherent and shared understanding of the competing demands of justice.

The authors work toward a common understanding by discussing first the progress made in addressing the interests and justice-demands of existing and future people and nonhuman organisms, and then the current state of knowledge and debates regarding those demands. The authors then discuss how conservation actions have at times involved insufficient attention to the rights and interests of existing people, especially those surrounding or previously within the protected areas. In doing so, the authors draw upon case studies to bring life to the human impacts of the conservation actions.

What is Justice?

Aristotle clearly established that just and equitable treatment is not necessarily equal treatment, as differing circumstances call for differing treatments. Accordingly justice and equity are considerably more difficult to agree upon and to achieve, in

part because a common understanding of merit – what a person deserves – has been elusive. To determine ‘justice as fairness’ in the treatment of people, Rawls (1999) has advanced the notion of the veil of ignorance, by which people are called upon to consider what distribution of circumstances they would prefer given that they imagine the experience of every person who might be affected by the decision. According to Rawls, this approach would better attend to concerns associated with the identities and number of people impacted by an action, which some argue and is ignored by utilitarianism. Like much of economics, utilitarianism seeks the greatest total goods regardless of the specifics of distribution. Utilitarianism may therefore imply preference for alternatives in which the disadvantaged are further disadvantaged, as long as the total gain is more. Utilitarians argue that the amount that people benefit from a given impact depends on their circumstances – for example, the poor benefit more from a dollar than do the rich – such that utilitarianism’s aggregation of benefits sufficiently accounts for equity. Other ethicists counter that justice must go beyond an aggregation of what people want for themselves (personal preference) and also attend to what people believe constitutes a just society (principle) (Sagoff, 1998).

Like many other ethicists, Rawls only intended to consider the treatment of people – “rational beings with their own ends and capable of a sense of justice” but efforts to protect biodiversity have been fueled largely by a notion of justice that extends to and beyond the boundaries of the community of existing people. Conservationists argue that the community of beings toward whom we have responsibilities (‘moral patients’ in philosophy) should include future generations, nonhuman organisms, and perhaps even ecosystems.

The authors do not defend a particular theory of justice. For our purposes it is sufficient to note that justice must involve a fair distribution of rights, responsibilities, costs, and benefits. And when actions have impacts with unfair distribution, justice requires appropriate restitution.

The implications of justice for moral acceptability is subjected to debate within ethics: utilitarianism assumes that an action is morally acceptable if injustices are outweighed by other gains, whereas other theories do not allow gains to offset injustices. Regardless, the just treatment of individuals has importance for all ethical theories.

Inclusion of Future People: Benefits of Conservation

The conservation of biodiversity is fueled in part by the recognition that actions taken by existing people for their own direct benefit have diffuse – but cumulative and consequential – impacts on existing and future people through the degradation of ecosystem services (the flow of benefits from nature to humanity). Often the loss of biodiversity and its associated benefits is a vehicle for injustice, as powerful capitalist or authoritarian forces sequester environmental benefits for themselves at the expense of those less empowered. Future people deserve special consideration in the context of biodiversity and its benefits because many losses of biodiversity are irreversible. Accordingly, conservation can and should ameliorate injustice and promote the equitable sharing of biodiversity's benefits across populations and generations. Efforts like the *Millennium Ecosystem Assessment*, 2005, which recognized the needs of people right from its conception, offer considerable progress for conservation in promoting socioeconomic justice.

Unlike existing people, who can be harmed physically or psychologically in the name of conservation, future people are affected primarily through benefits accrued and denied. Insofar as future people will inherit the harms experienced by their parents and grandparents, the authors consider these other dimensions of justice through the Section on Inclusion of Nonhuman Organisms.

Ecosystem services – as the benefits that people derive from ecosystems – provide a framework for the justice concerns of future people regarding biodiversity. Although the dependence on biodiversity of the supply and stability of individual ecosystem services varies considerably and is generally poorly characterized, ecosystem services nevertheless represent the best expression of the benefits of biodiversity. Ecosystem services can be grouped into five categories: provisioning, regulating, supporting, cultural, and option.

Provisioning

Degradation of ecosystems threatens the ability of existing and future people to provide for their material well-being through 'renewable' natural resources. The collapse and lack of recovery of fish stocks such as the northern cod demonstrate that ecological impacts can prevent some of these resources from being truly renewable. Recent research has revealed that we have removed the majority of the top predators from ocean ecosystems and are now harvesting less-desirable species lower

in the food chain ("fishing down marine food webs") (Pauly *et al.*, 1998). Conservation activities attempt to address such impacts through reform of fishery management, new technologies (e.g., turtle excluder devices, low-bycatch long-line practices), and marine protected areas (MPAs). Other natural resources are impacted similarly, such as forests, whose wholesale logging may trigger shifts to other forms of dominant vegetation, undermining the productivity of timber resources.

Regulating

Habitat destruction and climate change also diminish the ecological regulation of key biogeochemical processes and thereby the mitigation of damages to existing and future people. Loss of forests and wetlands impedes protection from river flooding; cutting and burning forests exacerbates climate change and its possible negative impacts; clearing of mangroves and loss of coral reefs and other coastal ecosystems undermine protection of coasts from flooding associated with tsunamis and hurricanes. Conservation activities aim to lessen these ecological insults through protected areas, best-management practices on private lands, ecological restoration or afforestation, and alternative land uses and livelihoods. Note that activities intended to mitigate one ecosystem service may have negative impacts on others: for example, afforestation in inappropriate (especially arid) locations may undermine water provision and harm biodiversity. Strategies such as biodiversity accreditation of carbon credits and management for multiple ecosystem services seek to redress these unintended consequences.

Supporting

Ecological degradation also undermines the services that are crucial for realizing value of other services, such as pollination, pest control, and prevention of soil erosion for agriculture. Because the implications of such service losses to future generations are not reflected in the functioning of current economic markets it is especially important that we plan specifically for such indirect, temporally distant effects. Some existing programs do attempt to limit or lessen soil erosion, such as the Conservation Reserve Program in the United States and the Grain-for-Green program in China. We need similar large-scale projects to protect populations of native pollinators and pest enemies.

Cultural

The loss of natural habitat and biodiversity gravely threatens the future contribution by ecosystems to the nonmaterial benefits people derive from human–environment interactions (including place value, cultural identity, and esthetic, artistic, scientific, and spiritual inspiration). Mostly to guard against this, numerous conservation nongovernmental organizations (NGOs) have targeted the protection of beautiful spaces and charismatic megafauna. Similarly, governments across the world have established protected areas that are more effective at protecting iconic but infertile landscapes than biodiversity,

and the World Conservation Union (IUCN) has established a network of World heritage sites for which cultural values are important contributors. To complement these various efforts, many governments have passed legislation protecting threatened and endangered species.

Option

Perhaps more worrisome than the threats to known services are the threats to ecosystems' provision of future values that we do not yet understand: the option values (recognized as a separate category of services by [Daily et al. \(2000\)](#) but not the [Millennium Ecosystem Assessment \(2005\)](#)). Plants like the rosy periwinkle and the Pacific yew were considered relatively unimportant until it was discovered that they are especially effective in treating childhood leukemia and other cancers for which medicines are lacking. Only by protecting a large component of biodiversity – including rare and inconspicuous organisms – can we sustain the options of future generations ([Mangel et al., 1996](#)). Such reasoning was a part of the motivation for the 1992 UN Convention on Biological Diversity, which commits nations to protect biodiversity within their borders and rich nations to assist less-developed countries in this task. Unfortunately, although much has been done, much has not – both within nations and between them.

Major unresolved philosophical issues impede the just treatment of future generations:

1. To what extent do we have responsibilities toward people whose identities depend upon our decisions (the future individuals paradox), we only need to ensure that their lives are worth living or do we have responsibilities beyond that ([Parfit, 1984](#))?
2. How should we deal with shifting baselines ([Pauly, 1995](#))? That is, if future generations grow up with less natural habitats or less-intact ecosystems, they may be satisfied with less than we might be, so how should we calculate our impacts on future generations?
3. To what extent are we responsible for the way that our actions might change the actions of future generations (impacting yet subsequent generations)? When changes are irreversible, most of us would agree that we are responsible for the impacts on all future generations. But if we degrade ecosystems and compromise the ecosystem services of future generations in a manner that is theoretically reversible, human psychology might nevertheless render it unlikely to regain the services, as restoration 'seems' much more onerous, uncertain, and supererogatory than protection. Should we apply a utilitarian approach to calculate the various expected direct implications of our actions or should we apply the logic of Immanuel Kant, according to which we should act only in a way that we would have all generations act? Although utilitarianism might seem to allow some generations to unsustainably harvest natural ecosystems and biodiversity, Kantian logic would seem to prohibit this.
4. What is an appropriate discount rate? To obtain mathematically bounded solutions and to reflect the expected improvement of material well-being, economists discount future costs, and benefits, assuming that foregone benefits

will be more easily substituted and that committed costs will be more easily borne ([Portney and Weyant, 1999](#)). (Note that this discounting to account for the interest on investments does not entail discounting the well-being of future generations through 'time preference,' which most ethicists rebuke). How is well-being likely to change and how can we appropriately account for our expectations and our uncertainties?

5. What will future people value? What is the relative value of general wealth (converted natural capital) versus (unconverted) natural capital; is it permissible to replace naturally provided ecosystem services with human-engineered services? If so, when and to what extent? The crux of this question seems to be how much future people will appreciate the cultural values associated with biodiversity, some of which seem much more difficult, if not impossible, to replace.
6. What does sustainability entail, and is it necessary in a moral sense, sufficient, or neither? Related to the above, there is a debate regarding the demands of sustainability. Weak sustainability would require us to ensure that future generations enjoy at least the same quality of life (allowing for substitution between natural resources and various other forms of capital), whereas strong sustainability would mean that future generations would enjoy the same level of natural resources. By Rawls' just savings principle, each generation would maintain its just institutions and preserve its material base and also commit savings beyond that, apparently requiring strong sustainability as necessary but not sufficient. However, utilitarianism seems not to require even weak sustainability: if we could benefit many future generations by slightly impoverishing the very next generation, utilitarianism seems to require this.
7. How might we think of justice not only as equity in distribution, but equity in the processes through which such decisions are made?

Inclusion of Nonhuman Organisms

Without necessarily subscribing to a particular theory of justice, many people feel that humanity's collective treatment of nonhuman organisms is deeply unjust and inequitable. Indeed, it is hard to imagine a theory of justice that recognizes the moral standing of any nonhuman organisms but that finds no fault in the pervasive loss of habitat and populations and the impending global extinction of some significant proportion of Earth's species. Widespread agreement on this injustice has contributed greatly to the major progress, the conservation movement has made. In recent decades, the protected areas network has grown considerably to 12% of the global land-base, thanks to the efforts of conservation NGOs and nation states. Many nations have signed the Convention on Biological Diversity and the Convention on International Trade in Endangered Species and numerous other conservation-related international agreements. On the downside, however, the existing protected areas are disproportionately situated on steep slopes with unproductive soils, in low-diversity high-latitude regions. And those that exist on paper are often not adequately enforced or managed,

such that species are routinely extirpated within their boundaries. Furthermore, protection of the marine environment has just begun, and freshwater organisms have been decimated. The imperiled state of biodiversity suggests that more remains to be done to ensure just treatment of nonhuman organisms.

Yet crucial issues remain to be resolved regarding the requirements of justice to nonhuman organisms, despite the considerable attention to environmental ethics (Primack and Cafaro, 2001):

1. There are numerous perspectives on which organisms and entities should have moral standing within a theory of justice. And what is the source of responsibilities we might have toward the nonhuman world? Nonhuman organisms, species, and ecosystems differ from people in a number of ways such that it is unclear that the responsibilities we have toward other people ought to be extended to these organisms. But if responsibilities to others (moral standing) do derive from some notion of sentience or consciousness (a capacity to feel or think), the uncertainty associated with nonhuman organisms (whether they possess that key characteristic) may itself incur moral responsibilities (Chan, *in press*).
2. What would constitute just treatment of those entities that merit moral standing (1)? What should we aim to protect, to what extent, and at what scale? Much conservation funding gets funneled through large international NGOs, whose actions seem largely aimed to conserve species richness at the global scale. Although both the Nature Conservancy and World Wildlife Fund have organized their conservation efforts by ecoregions, attention is focused on globally threatened species and ecoregions with many such species. Whereas, many governments at various scales have passed laws requiring conservation of species (and in some cases, subspecies) that are threatened nationally or regionally, though not globally. Many of these laws are intended to prevent extinction entirely, but many only require measures that have sufficiently small costs. Does the taxonomic level of species merit such a dominance of attention, or do populations and other levels deserve more concern than they currently receive?
3. What is the relevance of naturalness for the demands of justice? How important is it to protect species in their native surroundings and with their historic biological communities? And what should we do in the face of climate change, which is already shifting species distributions? How should we balance the needs of individual organisms with those of species and populations, and are the justice requirements different for domesticated or invasive species? These are crucial issues for ecological restoration, conservation, invasive species management, and environmental impact mitigation.

These various questions come to the fore in many conservation actions, such as The Nature Conservancy's much-publicized efforts to protect the Santa Cruz Island fox (and numerous endemic plants). This charismatic mammal is globally endangered, threatened most immediately by predation from golden eagles that were attracted by the presence of introduced feral pigs. To the outrage of some animal welfare

activists, The Nature Conservancy has been shooting the feral pigs to help dissuade the golden eagles from nesting on the island. This conservation action seems to reflect a valuation of species and naturalness over the welfare of individual animals such that conservation gains outweigh the injustices to the pigs. It is clear that there are still components of society willing to debate the appropriateness of this ethical stance.

Just Attention to Existing People: The Consequences of Conservation

If we accept that justice includes fairness in action, rules, and outcomes, then we must ask the following: are the same parties who benefit from conservation efforts those who bear the costs? And if not, what particular inequities must be attended to in the quest for greater justice in the protection of biodiversity? Currently, as areas are committed to biodiversity protection or are managed ever more strictly, extant communities' rights and access to land are often identified as primary threats to the integrity of the reserves. This threat-identification often occurs without consideration of issues crucial for just outcomes including livelihood needs in the face of a shrinking land-base, the availability of economic alternatives, and prior events such as the evacuation of people from the territories in question in the colonial period. Tension between human and biological priorities is especially strong when affected populations are primarily land- or sea-based (those with pastoralist, subsistence-agricultural, or fishery-based economies) and economic alternatives are nascent or elusive (West and Brechin, 1991; Leitmann, 1998; Salafsky and Wollenberg, 2000). We must also remember that indicators of biodiversity and species health are not solely status reports on physical conditions. They are imbued by values that are the products of a modern industrial world that seeks new markets in the form of wilderness experiences at same moment that it has come to recognize the loss of the 'frontier' and "nature" and now aspires to curtail that loss by restricting the activities of others (Igoe *et al.*, 2010).

Ultimately, most of the human societies value and work to preserve some aspects of biodiversity, and such efforts may be sufficient without outside involvement (Schwartzman *et al.*, 2010). Nonetheless, restrictions imposed by conservation efforts often involve imposing a postindustrial notion of value on those who are largely outside modernism's beneficial reach. We also cannot simply leave the recognition and restitution of injustices to those who raise its specter because the capacity to resist unjust practices is a function of power such that those with a greater ability to articulate their grievances are also those most likely to achieve desirable outcomes.

Distribution of Risks by Class, Gender, and Ethnicity

Our call for justice for human communities in conservation contexts follows the general principle of environmental justice. Poverty advocates argue that the costs of biodiversity protection are unfairly concentrated in the poorest regions of the world and can exacerbate poverty among women and other disadvantaged parties, and that when conservation

benefits do accrue, their local distribution is disproportionately secured by local elites. Thus, distributional injustice expresses itself both within and between communities at a variety of scales. Globally, the overrepresentation of biological hotspots in poor areas (e.g., the tropical Andes, Mesoamerica, Madagascar, and Brazil's Atlantic rainforest) has placed an unprecedented burden of expectation on nation states least equipped to meet conservation goals (Balmford and Whitten, 2003). This inequitable distribution of biodiversity hotspots has the potential for even greater injustice because the beneficiaries of the extractive industries that threaten biodiversity in such places are often not those who suffer its costs, and are often from comparatively wealthy populations in the developed world. Nationally and regionally, it is difficult for poorer nations to resist the inflow of foreign currency promised by an ecotourism industry enabled by protected areas – just as it is difficult to resist monetary benefits promised by extractive industries. This is the very income necessary to build infrastructures of protection and regulation and to reshape a nation's land-base toward conservation objectives, but the sustainability of such infrastructure and reshaping depends upon a base level of well-being among local people that is often lacking. It has been demonstrated too infrequently that the wealth produced by conservation-based development is redistributed to those human communities that are most affected by such land-use change.

The case of Madagascar's Ranomafana National Park offers a particularly alarming example of these distributional injustices (Harper, 2002), making it illustrative but not typical. Home of the golden bamboo and greater bamboo lemurs, the park, was established in the mid-1990s with an ambitious plan to reorient the economic structure of 26 adjacent villages. The intent to establish a park that also bettered the lives of local people was certainly active from the earliest stages. The intended benefits included the promise of health care to compensate for the loss of land and its anticipated accompanying local storehouse of medicinal plants; it also involved the substitutions of 'swidden' or dry rice cultivation with more intensive wet rice cultivation in the hope that this would produce greater yields and so both staple and market-ready grain. In fact, sustained health care was only offered in the form of birth control to minimize population growth and a very limited acute care wherein a traveling physician was assigned to 60,000 residents made occasional visits to dispense limited medicines. Health status among the local population deteriorated more generally both because of diminished land-based income and because the vision of a renaissance of traditional plant-based medicines (in the absence of alternatives) was more of a conservationist fantasy than a contemporary or a historical reality. For the vast majority, the imagined income from crop intensification did not materialize. Problems were exacerbated by the expansion of Betsilo peoples into remaining Tanala land, where the former possessed the necessary resources to take over the irrigated fields of the impoverished Tanala. Further, those who were able to cultivate irrigated rice were sanctified by conservation agents as progressive and modern, whereas long-standing hillside (dry) cultivation was deemed a quaint but destructive tradition or a 'cultural' (namely 'Tanala') predisposition unworthy of economic and social support.

The park itself has also led to an increase in local poverty as a function of pre-existing gender and caste-ascribed positions. The constant and often all-consuming labor owed in exchange for the use of rights for wet rice cultivation is often the basis for indebtedness to better-off landowners. This indebtedness most severely affects older single women who do not have male household members to fulfill these economic obligations and whose status is further compromised by reduced access to swidden (dry-cultivation) fields due to the park. Only a very small set of local elites benefited economically from the park. Not coincidentally, these few were instrumental in the park's genesis and did not have to relinquish land in the formation of the park. Most lost the right to future claims to forested land, but again the elites recovered more easily and fully by absorbing the land belonging to others – as that land was forced into sale – or by using the land of those who had become desperate and so would accept minimal rental sums (e.g., US\$12.50 for a three-year period). Justice in the above and other parallel cases requires that we remain diligent about the weighting of conservation's costs and benefits, asking repeatedly, whom does this act benefit and for whom does it cost, particularly at local scales? And, how can sustainable systems of restitution be brought into place quickly?

Distribution of Action, Responsibility, and Power

Anthropologists have also pointed to the problematic nature of the neoliberalisation of conservation. Broadly stated this refers to the conversion of most decisions to those legitimized by market success and measures, thus tending toward a commodification of all of nature's flows or services. But more critically, it also refers to the fact that some of the largest funders of major conservation NGOs, which are responsible for a great and growing proportion of conservation worldwide, are companies implicit in the transformation of ecosystems to intensive use (Chapin, 2004). Although we recognize that good citizenship and hazardous corporate or industrial practices might well co-exist, the danger is that corporate-NGO alliances can also mask or lead to a downplaying of heinous practices on behalf of corporate entities. An illustrative example (Igoe *et al.*, 2010) is McDonald's Endangered Species Happy Meals campaign. "Although awareness among children of biodiversity loss may well prevail as a result, the environmental contradictions of the fast food industry are far more pervasive and integrated than a Hotspots and Happy Meals partnership can even begin to capture. The rise of the fast food industry in North America is inextricably linked to automobile culture, expanding networks of superhighways, and the industrialization of global food production systems" (*ibid.*, p. 505).

Such collaborations between those NGOs who act to protect biodiversity and those companies responsible for losses of biodiversity deserve scrutiny. On the one hand, who better to fund biodiversity conservation than those who bear responsibility for the motivating problem? This is the logic of the 'polluter pays' principle. On the other hand, there are dangers that (i) the attention to the voluntary positive actions will distract public attention from behavior and actions that degrade biodiversity (Igoe *et al.*, 2010); (ii) conservation

organizations will have an incentive to turn a blind eye on any such behavior and actions, lest they bite the hand that feeds them (Chapin, 2004); (iii) the governance principles and mindsets that fuel a preoccupation with economic growth – which have largely been adopted by major conservation NGOs – will remain unchallenged despite their possible roles in creating the problems at hand (Corson, 2010); (iv) both the extractive industries and now their conservation – through the restriction of access to wild living resources – may represent competing major threats to the autonomy and sovereignty of people who depend on ecosystems for their livelihoods and well-being.

Reflections on the Distribution of Values: Cultural Sovereignty versus Cultural Naiveté

A justice lens on human communities also requires us to recognize that all conservation projects are also projects of social engineering: We need people to abide by new rules, change what they do, alter their livelihoods, and so on. Although social and biological change is impossible without these engineered consequences, there is a sustained failure among many conservation efforts to comprehend the injustice of the under-recognized clash of values. Biodiversity is not a value-neutral construct despite the widespread desire to avoid wanton destruction and maintain the health of needed ecosystems. By now biodiversity discourse is too deeply embedded in concomitant notions of ‘ideal natures,’ ‘good’ and ‘bad’ cultural practices, and utopian visions (e.g., the hoped for discovery of plant pharmacopias or the protection of primordial nonhuman landscapes). Comprehending the clash of values requires consideration of the implicit prescriptions of ideal behavior that accompany conservation projects and thus become the basis for the apportionment of benefits among the local population. Most extreme is the complete exclusion of local people in the pursuit of idealized ‘prehistoric’ landscapes as realized not through joint intent but ‘fortress conservation’ (Brockington, 2002). Subtler examples of culturally naïve expectations are that hunting with spears is acceptable – even culturally authentic – whereas hunting with guns is not, and that harvesting medicinal plants is viable whereas foraging for sustenance is not. Justice can only be served by recognizing our assumptions, their historical roots, and the judgments of desirable behavior that follow. Only then does it become possible to appropriately negotiate values in the prescription of acceptable practice. Goals regarding biodiversity outcomes – which fuel the conservation-derived prescriptions of behavior – are clearly a key component of conservation action; but these too require collaborative negotiation, adaptive management, and some hybridization of local and non-local practices, knowledge, and values (Chan *et al.*, 2007).

The Distribution of Rights, Title, and Access

Common property scholars have long attended to the importance of rights, expressed as control over the products and decision making pertaining to local resources. More recently, access has become the central point as this concept highlights the broader social contexts that permit or deny a person the

ability to benefit from ‘things,’ be they material or symbolic resources (Ribot and Peluso, 2003). Further, access to resources is fundamental to one’s capacity to achieve and maintain a land- or sea-based livelihood, which is itself embedded in a complex web of cultural and social arrangements. Thus, the distribution of access to resources is central to theorizing justice although the processes underlying this distribution are less visible than is the assignation and ‘evidence’ of legal title. Use rights are often assigned through oral contract or customary practice, and it may also be mediated through lineage ties, village or religious leaders, or normative pressures. Knowledge of these dynamics is not readily available to conservation agents or even expressed by local people, for whom it has long become an inarticulable common sense. Yet use and access is also tied to systems of power, which may themselves be unjust (Asfaw & Satterfield, 2010). Changing access to achieve conservation is hazardously conducive to blind injustice in that something as seemingly simple as the individualization and legal titling of access rights to property (also a feature of aid and development agendas, and neoliberalism generally) may involve a fundamental shock to the social system.

Even where a system of individualized property rights is firmly established, individuals’ rights to take actions that degrade ecosystems and threaten biodiversity are highly contentious. For example, in the United States there is a strong anti-Endangered Species Act property rights movement, which claims that the federal government has no business dictating what a landowner should or should not do with his or her own land. Is it just to force property owners to bear the costs of conservation, just because they were ‘unlucky’ enough to host endangered species? Such perceived injustice has fueled the common practice of “shoot, shovel, and shut up” for endangered species, because landowners can often escape responsibility when endangered species are not shown to inhabit the property in question. In recognition of these equity concerns, the NGO Environmental Defense and the US Fish and Wildlife Service have instigated several programs that alleviate the burden on landowners (Wilcove and Lee, 2004). In other countries such as Canada, the United States experience has led to a shying away from endangered species legislation pertaining to private lands.

Colonial Legacies and Restitution

Throughout the developing and developed world there exists the undeniable legacy of colonialism in the conception of biodiversity and its conservation. For instance, many national parks were established for the benefit of colonial administrations but have since become important cornerstone landscapes for the benefit of biodiversity. Yet, the populations evacuated from such sites have both living memories and oral records of these injustices. And such injustices are often the basis in the contemporary period for severely degraded relations between the nation state and conservation NGOs, as well as for intertribal or intercommunity conflict. The iconic Serengeti National Park in northern Tanzania offers a case in point (Neumann, 1998). The colonial period itself saw increased disruption of customary land use and practices in the

form of restricted access to hunting and forest resources. By the end of the colonial period, ordinances pertaining to the new network of national parks went so far as to exclude traditional and land-based people entirely. "Under this ordinance, the Tanganyika National Parks become for the first time areas where all human rights must be excluded thus eliminating the biggest problem of the Trustees and the Parks in the past" (Neumann, 2000, p. 125). Serengeti National Park was less a product of the local colonial administration, which recognized the hardship such parks would generate, than of international conservation organizations operating in the 1920s and 1930s, whose vision of what Africa should be was a mythical unspoiled wilderness, rhetorically explained as an effort to save species from extinction. In fact, the displaced (particularly Maasai pastoralists) watched the beneficiaries parade by with prized game whereas poverty and intertribal conflict came to characterize those on the periphery. In a 1957 memo, a Maasai observed, "From time to time we see (white) hunters passing with the trophies of animals that they have shot. It is the same people and their friends who wish to evict us from the National Park, yet we think it is they who are the enemies of game rather than us" (quoted in Neumann, 1998).

In settler nations with significant Aboriginal populations, such as the United States, Canada, New Zealand, Australia, Brazil, Chile, and so on, many heretofore unresolved Aboriginal treaty obligations are closely tied to the establishment of national parks. Some parks were used to justify placing Aboriginal populations on reservations. More recently, some parks have become a means of settling conflicts over traditional territories, but in doing so they also confine Aboriginal populations to limited use of those areas as prescribed by conservation objectives. In South Dakota, the Lakota Sioux have been pushed aside for a series of mining interests and are now faced with the possibility that the land left aside by the extractive industries will be managed for conservation, thus continuing and deepening injustices. The Sioux have not accepted compensation monies, and instead seek the recovery of treaty lands, the recovery of the bison, and the restoration of mountains they deem sacred. The dispute has unfortunately pitted recreational users of the area against the Sioux Nation and has produced such acrimony that the council of the nation "describes the United States as an imperialistic power that has sought to undermine, diminish and abolish not only the Lakota land-base but Lakota rights to self-sufficiency and self-determination" (Halder, 2003, pp. 105–107).

The failure to recognize past injustices often impedes successful community-based conservation, as does the failure to establish meaningful local control over the governance of a conservation area (Timko and Satterfield, 2008). And it is difficult at best to sort out the historical contingencies that invariably complicate any new conservation effort (including which populations or lineages have decision authority over particular parcels or goods derived from within these) (West, 2006). At the very least, justice will require a vastly deeper historical understanding of the local trajectories and consequences of both colonial legacies and associated programs of human evacuation. Such an understanding will enable a vastly improved system of recompense, where the primary

goal of negotiation is not solely cash for land, but the recognition of the legitimacy of historical claims and the provision of substantive decision-making control over future uses, regulation, and access to benefits.

Conservation efforts are further complicated by histories of war and genocide. In such postconflict societies, both the land and the people are often traumatized, and the nation states in which they are embedded tend to be comparatively unstable. Central Africa, home to some of the remaining populations of great apes, offers cases in point. Such settings pose a particularly vexing set of problems as concerns justice. In some cases, poverty and sustained human degradation have fueled desperate measures, including the consumption of great apes and other endangered species as "bushmeat," and the further degradation of any available resources. And yet, no one (human or otherwise) will be served in the long run by equally desperate measures to secure conservation by continued force.

Conclusions

Towards the end, the authors agree with Zerner (2000) that biodiversity conservation depends on the development of solutions that are socially just and ecologically informed. As a society, we should strive for sustainable economic development wherein biodiversity conservation is pursued – for its global and future benefits and for its own sake – in harmony with the cultural, social, and economic well-being of local peoples.

Life Cycle Analysis of Biofuels

Jason Hill, University of Minnesota, St Paul, MN, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Biofuel Liquid transportation fuels derived from plants or other biological materials.

Carbon footprint Life cycle analysis in which climate change is the impact category of concern.

Functional unit Quantity of reference for comparing two or more products based on their equivalent use.

Life cycle analysis Method of quantifying the suite of environmental effects associated with the production and use of a given product.

Market-mediated effect Changes in the supply and demand of other products due to the production of a given product.

Supply chain Those stages in the production and use of a given product through which materials and energy flow and can be traced.

System boundary The set of processes under consideration in a given life cycle analysis.

Introduction

Life cycle analysis (LCA), also known as *life cycle assessment*, is a method of quantifying the environmental impact of products such as biofuels. In LCA, researchers prepare an inventory of the resources used (e.g., fossil fuels and raw materials) and the substances generated (e.g., greenhouse gases, solid waste, and other pollutants) throughout the full life cycle of the production, transport, and use of the product of interest. From this inventory, researchers prepare an impact assessment that estimates the ultimate effects on human health, ecosystem function, and natural resource depletion. Because LCA considers the entire product life cycle, it is useful both in identifying major sources of environmental impact in a product's supply chain and in mitigating them (Graedel, 1996; Curran, 2008).

The first LCA study is widely held to have been conducted in 1969 by Teasley, who was examining different beverage container options for the Coca-Cola Company (Hunt and Franklin, 1996). To this day, LCA is predominantly used as a comparative tool by corporations, marketers, regulators, and consumers for making informed choices. Liquid transportation biofuels are typically compared against conventional petroleum-derived fuels such as gasoline, diesel, and aviation fuels (Farrell *et al.*, 2006; Stratton *et al.*, 2011). Comparisons are also made between biofuels and alternative uses for biomass such as bioelectricity (Campbell *et al.*, 2009; Ohlrogge *et al.*, 2009).

Types

Various methods for conducting LCA exist, each of which has particular strengths and limitations. One major albeit subtle distinction lies in whether the goal of an LCA study is to assign responsibility for environmental impacts to a given product or whether the goal is to estimate the net change in environmental impacts as a result of a decision to produce a product (Finnveden *et al.*, 2009). The first of these, commonly known as an *attributional approach*, takes the total environmental

impact of human activity and seeks to ascribe responsibility for a portion of it to a given product, which may include its entire supply chain or selected parts of it (Weidema, 2003). The second, commonly known as a *consequential approach*, takes the total environmental impact of human activity and seeks to understand how it expands and contracts as a result of producing and using a given product (Earles and Halog, 2011). An attributional LCA is, therefore, arbitrarily defined as a function of how system boundaries are drawn, typically limited by space, time, or stage in a supply chain. It is of primary use to engineers looking to improve process efficiencies or to marketers comparing among purchase options. Alternatively, consequential LCA has infinite system boundaries, which is essentially the same as saying there are no system boundaries. It is strictly defined as the entire suite of direct and indirect impacts, regardless of where or when they occur. It is of primary use to policy makers and regulators who are concerned with the cumulative and comprehensive effects of product decisions.

Attributional LCA is typically conducted using process-based models, input-output models, or a hybrid of the two. Process-based models measure environmental flows along a given supply chain, including processes flowing therein and therefrom. Process-based models offer a fine resolution and product-specific results but typically have narrow system boundaries so as to be tractable and representative of the supply chain under which corporate control may be exerted. By contrast, input-output models utilize data both on trade among sectors and the environmental impact of each of these sectors to allocate environmental impact to a product produced in a given sector (Leontief, 1970; Lave *et al.*, 1995). These models offer much broader system boundaries (e.g., the entire economy of a nation) but present a coarser view, leaving the impact of a product unresolved within a given sector. Hybrid approaches also exist that supplement product specific data from process-based models with data from the expanded system boundaries of input-output models (Suh and Huppes, 2005).

Consequential LCA is methodologically similar to hybrid attributional LCA but with some key differences (Ekvall and

Weidema, 2004). First, consequential LCA takes a dynamic view of the world unlike attributional LCA, which takes a static view. As such, the physical flows in consequential LCA are described using marginal data, whereas attributional LCA uses average data. Second, consequential LCA incorporates economic modeling to describe changes in environmental impact that occur beyond the direct supply chain and use of a given product, including those that occur as a result of market-mediated effects such as economies of scale, substitution effects, and elasticities of supply and demand (Earles and Halog, 2011; Girod *et al.*, 2011). Conversely, attributional LCA is not concerned with economic modeling beyond either allocation of material flows to coproducts or, as is specific to input-output and hybrid approaches, descriptions of existing trade flows. Third, attributional LCA describes a single state of environmental impact (i.e., the world at a given point in time), but consequential analysis by its very nature requires more than one scenario, typically a world in which an item is not produced (i.e., a baseline) and a world in which it is (i.e., the baseline plus the delta). Overall, consequential LCA is inherently more difficult not only because it requires marginal data and economic modeling, but also because it requires analysis of at least one scenario that has not occurred. For retrospective consequential LCA, which is LCA looking at past decisions, this would be the counterfactual (i.e., that which did not occur, whether it be with or without a given product). For prospective consequential LCA, which is LCA used as a predictive tool for estimating future impacts of current or future decisions, this would be at least two scenarios (i.e., the world with a given product and the world without it).

Standardization

Extensive efforts have been made to standardize LCA methodologies. Still, the need to maintain flexibility in its application by different stakeholders is well recognized. Standardization has therefore focused primarily on defining commonly used terminology and ensuring that essential elements of LCA are reported consistently and transparently. The commonly used ISO 14040 series defines LCA as consisting of four phases: goal and scope definition, inventory analysis, impact assessment, and interpretation (ISO, 2006a, b). In the first phase, the goal and scope definition, the system to be studied is identified and described, the system boundary is established, and critical assumptions and limitations are stated. The choice of a functional unit is also explained so as to ensure a proper basis for comparison among different products based on how they are used. For example, a comparison between bar soap and liquid soap should not be made on each package's weight or volume but rather on the basis of an equal number of hand washings. In the case of biofuels, comparisons between ethanol and gasoline are typically made on a per unit energy (e.g., megajoule (MJ) or British thermal unit (Btu)) or per distance driven (e.g., kilometer or mile) basis rather than on a volumetric basis (e.g., liter or gallon) because ethanol has approximately two-thirds the energy density of gasoline (Liska and Cassman, 2008; Cherubini and Strömman, 2011).

The second phase, the inventory analysis, consists of gathering and compiling data on the physical flows of materials and energy throughout the product life cycle as defined by the chosen LCA methodology. In attributional LCA, this includes flows through the supply chain; in consequential LCA, this includes both supply chain and market-mediated flows. In this phase, decisions regarding the appropriate allocation of multiple product streams originating from a single process are also made. In the case of biofuels, this includes the coproduction of ethanol and animal feed from the corn fermentation process or the coproduction of ethanol and electricity from the sugarcane ethanol production process.

The third phase, the impact assessment, seeks to quantify the environmental effects of the changes in physical flows resulting from any supply chain and any market-mediated changes in material and energy as estimated in the inventory analysis. First, impact categories are chosen, which may include climate change, acidification, eutrophication, biodiversity, human health, fossil fuel depletion, and land and water use, among many others (Bare *et al.*, 2003; Curran *et al.*, 2011). Second, characterization models are used to estimate the effect of the inventory analysis on these impact categories (De Schryver *et al.*, 2011). Third, these effects may be compared via normalization, grouping, and weighing. Such comparisons may be useful for assessing trade-offs but may involve value judgments (Gloria *et al.*, 2007).

The fourth phase, interpretation, is an ongoing process throughout all the other three phases. Checks for completeness, sensitivities, and consistencies are to be performed, and any conclusions and recommendations are to be stated.

History and Application

Early application of LCA to biofuels grew from a desire to verify potential reductions in fossil fuel use. The 1970s energy crisis spurred great interest in finding alternatives to petroleum, particularly for use in transportation. Early work such as that of Chambers *et al.* (1979) therefore focused on the fossil energy balance, also known as the *energy return on investment*, of biofuels. Studies also considered the related metric of their petroleum balance, which essentially measures the amount of usable liquid transportation fuel returned from biofuel production. Interest in biofuels as a means of increasing domestic liquid fuel production continues to this day (Hammerschlag, 2006).

More recent application of LCA to biofuels has increasingly focused on environmental impacts beyond fossil resource depletion. Climate change has received particular attention. An LCA in which greenhouse gases inventories are prepared and expressed in CO₂ equivalents is commonly known as *greenhouse gas accounting*, *carbon accounting*, or *carbon footprinting* (Peters, 2010). Estimating net greenhouse gas emissions relative to conventional alternatives has dominated the use of LCA in biofuels research for two main reasons: (1) recent interest in climate change mitigation has been intense, and (2) the fossil fuel inventories (e.g., total use of coal, petroleum, and natural gas) generated when calculating net energy balances of biofuels can readily be translated to greenhouse gas inventories of major climate-forcing species

of interest, including carbon dioxide (CO₂), nitrous oxide (N₂O), and methane (CH₄). Beyond fossil fuel use, additional sources of greenhouse gas emissions that must be tracked when calculating greenhouse gas inventories to include N₂O emissions from nitrogenous fertilizer production and use (Howarth *et al.*, 2002; Hill *et al.*, 2006), CO₂ and CH₄ emissions from any changes in soil carbon storage in biomass production (Johnson *et al.*, 2007; Cherubini, 2010; Karlen *et al.*, 2011), and CO₂ emissions from any changes in land use that may occur (Fargione *et al.*, 2008).

Beyond fossil resource depletion and climate change, other major impact categories explored in biofuels using LCA include water use (Dominguez-Faus *et al.*, 2009; Wu *et al.*, 2009; Chiu *et al.*, 2011; Scown *et al.*, 2011; Yeh *et al.*, 2011) and air quality (Hill *et al.*, 2009; Huo *et al.*, 2009; Tsao *et al.*, 2011). Biofuels examined in these impact categories include first-generation biofuels produced from feed and food crops such as corn and sugarcane, second-generation biofuels (e.g., ethanol produced from lignocellulosic biomass), and advanced biofuels (e.g., hydrocarbons produced from algae) (Wu *et al.*, 2006; Huo *et al.*, 2009; Fargione *et al.*, 2010; Roberts *et al.*, 2010; Brentner *et al.*, 2011; Savage, 2011). Analyses suggest that in general the biofuels with the most beneficial impact will include those produced from crop and forestry wastes and residues, as well as from dedicated perennial crops grown with low agricultural inputs on marginal or abandoned croplands (Tilman *et al.*, 2009; Spatari and MacLean, 2010; Wiens *et al.*, 2011).

Use in Policy and Regulation

Recent years have seen an increase in a desire to apply LCA in biofuel policy and regulation (DeCicco, 2011). The renewable fuel standard of the US Energy Independence and Security Act of 2007, for example, sets greenhouse gas reduction levels for biofuel consumption volumes. Triennial reports to the US Congress describing the effects of increased biofuel production on other impact categories are also mandated. LCA is also employed in the regulation of the California low-carbon fuel standard (Sperling and Yeh, 2009; Boies *et al.*, 2011). Use of LCA in policy making and regulation has engendered a shift away from attributional approaches toward consequential approaches, where the full set of impacts resulting from a decision is taken into account. To date, studies that have taken a full consequential LCA approach to evaluating biofuels are lacking. Many studies utilizing attributional LCA have begun to incorporate elements of consequential LCA so as to approximate environmental changes that may be expected under increased biofuel production. For example, models have been adjusted to include indirect effects commensurate with large increases in land use for biofuels and any resulting indirect land-use change (Wang *et al.*, 2007, 2011). Others have focused on the marginal displaced energy sources (Lemoine *et al.*, 2010; Yeh *et al.*, 2010) and elasticity in transportation fuel markets (De Gorter, 2010). Use of LCA in policy and regulation has also prompted inquiry into means of incorporating variability and uncertainty into the decision-making process (Mullins *et al.*, 2011; Venkatesh *et al.*, 2011).

Glossary

Contingency Possibility or uncertainty; an event that may occur but is not likely.

Ecocriticism Interdisciplinary study of literature, history, religion, and philosophy with an emphasis on places, evolutionary biology, and environmental problems.

Etiology The study of causes or origins; stories that explain the origins of phenomena.

Land ethic Valuing land as part of a biotic community, not merely as property.

Literature Imaginative and crafted writings, in the form of poetry, prose, fiction, or drama.

Nature The material world and the physical forces or processes that control it.

Pastoralism Agrarian life and work; also literary accounts of rural life, often simplified or idealized.

Places Areas of space with human association; also positions of status in society.

The idea of biodiversity traces back to early concepts of variety and unity, which have their sources in history, philosophy, and literature. These cultural fields have recognized the need for biological variety since the first days of recorded time. Literature comprises many acts of language, from ancient folk chants to poetry on the Internet, often for entertainment and instruction, the *dulce et utile* praised by Cicero in his writings on rhetoric. The main goal of literature is to expand and extend the human imagination. By simulating experiences and performing ideas, literature helps affirm the value of diverse places and species, through a wide range of styles and themes. Not all writings are considered literature, just as all experiments are not science. Like professional science, the ideal of literature implies standards of custom and cultural decree (Turner, 1985)

Literature and Science Relations

Over the centuries, literature has come to mean imaginative writing, the product of disciplined craft that creates drama, fiction, poetry, or essay. Critical theorists disagree as to whether the prime agent in literature is content or form, conveying a message or shaping an attractive verbal structure, like a story or a poem. In the balanced formula of British poet and critic Samuel Coleridge, poetry is “the best words in the best order,” which affirms that an ideal of quality guides literary writers. But “quality” is an intrinsic value, one that clashes with the extrinsic aims of science. Science seeks an unbiased view of what nature is and how it operates, while literature observes those conditions through the filters of human belief and emotion.

Although novelist Snow (1959) believed that science and literature are opposing cultures, recent observers find more congruency in their aims. Both disciplines use observational methods to detect patterns and to record them for the benefit of posterity. Biologist Gould (1989) sees science and literature as forms of historical narrative that describe contingency, the recording of uncertain, unexpected events just beyond current knowledge. Literature uses contingency in plot sequences – as events connect and readers turn pages “to find out what

happens next.” Scientists unravel nature’s “plots” by re-constructing them as predictive narratives.

Literary forms represent natural diversity with varying degrees of accuracy. Drama is imprecise because it relies on social situations and voiced sentiments, enacted on a physical stage. Painting and photography may document a place or species, but pictures without words are not sufficiently interpretive. Poetry (whether epic or couplet) and the various forms of prose (novel, story, essay, memoir) are considered more comprehensive because they both describe and evaluate, mingling sensory experience with calculated thought. The meaningful connection of image and word: literature pursues that goal in order to represent biodiversity for the benefit of human understanding.

Language in Science and Literature

Human beings share a common attribute in language, the instrument they use to construct meanings. The path of language moves from variety to unity: many words exist; when combined they form phrases that express thoughts. A thought may be social or personal, as it creates a send-and-receive cycle that communicates. To meet the human need to understand both surface and depth, literature often asserts that natural objects are not alien but connected to human emotions. As Henry David Thoreau wrote in *Walden* (1854), “Shall I not have intelligence with the world? Am I not vegetable mould myself?” Seeking knowledge of nature’s variety is thus a mutual goal for literature and science, but sharp differences exist in their methods.

Scientists prefer to use words precisely, to convey strictly limited meanings. Literary writers recognize that words have long histories, in which meanings change across time and space. As philologists learned in the nineteenth century, words behave like organisms (growing from root to stem to branch; cross-breeding; and migrating to other habitats). Some words are viruses, infecting a host, while others lie in dead heaps, like sediment. Through these morphological changes, words shape human values to form and reinforce perceptions, beliefs, and opinions.

Words are also representational, using speech sounds to create signs for rain, snow, leaf, and rock. Combinations with other words produce symbolic and metaphorical overtones, suggesting layers of possible meaning. Ezra Pound's haiku-like poem, "In a Station of the Metro" (1916), compresses a startling comparison of culture and nature into two lines: "The apparition of these faces in the crowd;/Petals on a wet, black bough." Such powers of analogy give words a suggestive and speculative function, which lends itself to stories with a didactic purpose.

Etiological Tales of Nature

The earliest surviving fables and myths are etiological tales, told to explain how the world began, why rain falls, and when crops will bloom or die. Among prehistoric people, nature stories about diverse and complex phenomena became a form of cosmology, providing the basis for ritual ceremony, whether for medical or spiritual healing. Early ideas of disease, as a condition of imbalance or disharmony, encouraged the symbolic belief that the earth was also a vast 'body' that may be cleansed and healed. Some observers (Buell, 1998) note that medicinal rhetoric continues to shape current discourse on toxicity, pollution, plague, and other forms of ecodisaster.

Early tales are efforts to define the myriad natural forms that shape everyday life, from land and species to climate and seasons. At the same time, literature may portray human efforts to resist or control nature, commonly through acts of labor and art. Farmers drain wetlands in order to plant crops on dry land. They weave nets to lift fish from the sea, then bury the fish with seeds to help new life emerge. Stories about these actions form early contributions to understanding biodiversity by recognizing the complexity of nature and the intricacy of its related elements. In a Navajo creation tale, "Changing Woman and Her Hero Twins," the storyteller pours tinted sands on the earth, forming a series of objects and events that are as multiple and shape shifting as the identity of Changing Woman, an earth goddess who has the power to create.

Yet by emphasizing human impact, many early stories also teach that humans and nature are divisible and separate. That idea is distinctly Judeo-Christian and supports the very concept of "nature," meaning all that is born, rising from a source. No equivalent term appears in Asian culture, where the physical world connects humanity to the wider universe (Torrance, 1998). The Old Testament tells two different stories of human creation: man is made separately, in the image of God (Genesis 1:26), but is also formed from dust (Genesis 2:7). The first story appears to justify human dominion over other creatures, while the second suggests a humbler bond with the earth. Belief in a separate, special creation of human beings continues to guide modern fundamentalists, who fiercely resist Charles Darwin's unitary theory of evolution. By including two narratives, the Bible leaves open the problem of literal versus metaphorical interpretation.

Pastoralism in Poetry and Scripture

In the early civilized era, 4000–500 BC, ideas and tales of nature's variety emerged from the extractive activities of

hunting, fishing, farming, herding, logging, and mining. By learning to harvest natural materials and process them into goods, humans became experienced observers of seasonal events, of plant and animal lives, and of locations favorable to cultivation. Land use and property rights became the basis for literacy, trade, law, and tribal identity (Crumley, 1994). Nations root themselves in physical places, and when people are forcibly displaced, as in the case of the early Jews, they endure their nomadic years with consoling legends of a Mesiah, a warrior-shepherd who will return them to the lost homeland. Such early stories reveal a basic function of literature, to reflect the value of places and how human presence changes them.

In the Old Testament, land is an element made by God, then granted to humans to clear and own. They receive this gift in innocence, but later sin and must accept the burdens of mortality: labor, pain, disease, and death (Genesis 1–3). The status of wilderness is even less benign: uncultivated places, like mountains and deserts, display God's power and offer a test to the faithful. In the story of Noah (Genesis 6–9), God directs Noah to build a great Ark and bring to it at least two of every creature that lives, male and female. Then God floods the earth with rain, until only the Ark and its inhabitants survive. The story illustrates not just divine power, but also how human stewardship may preserve the earth's vast diversity of species. The later vision of Isaiah predicts a savior who will restore the earth to its unfallen state, when all species live together in harmony: "The wolf also shall dwell with the lamb, and the leopard shall lie down with the kid; and the calf and the young lion and the fading together; and a little child shall lead them" (Isaiah 11:6). This scene, oft painted by the nineteenth-century Quaker artist Edward Hicks, represents the differences between a creation marred by original sin and one healed by the world's innate bounty.

In times of constant social change, literature offered comforting accounts of bygone days and places. The very concepts of city and country, or urban and rural land, arose out of literature that invested both realms with a complex relation, possessing zones and boundaries of separation but also connection (Williams, 1973). As urban centers grew into the great city-states of Alexandria, Athens, and Rome, the poets Hesiod, Theocritus, and Virgil wrote pastoral poetry, a literary form known variously as bucolic, georgic, and eclogue; verses that portray rural life as gentle, principled, and close to the soil. Jesus of Nazareth also adapted pastoralism in his parables about fish and seeds to preach transcendence of earthly limitations, a literary device equally effective with audiences in rural Judea and in the fast-growing cities of the Mediterranean basin.

After the Roman empire shifted from paganism to Christianity in the third century AD, early Christians saw their pastoral mission as spreading the Gospels throughout Europe. Monastic enclaves preserved both classical science and literacy in the Dark Ages (400–800), between Rome's fall and the revival of learning in courts and cathedral towns. During the Middle Ages (800–1400), infectious plagues reduced populations and relieved pressure on Mediterranean ecosystems, still recovering from Roman-era deforestation, erosion, and pollution (Hughes, 1994). Medieval literature and science became twinned endeavors, as clerics and scholars sought to

describe the fixed Ptolemaic universe, an effort that culminates in Dante's epic poem, *The Divine Comedy* (1321). Medieval culture's fascination with alchemy likewise fed early studies of natural history and chemistry, described in several of Chaucer's *Canterbury Tales* (1400).

Colonial Expansion and Taxonomy

Chaucer's use of folk tales reflects the popular literacy that spread rapidly after Johannes Gutenberg invented movable type (1455), as printed tracts, manuals, and libraries of books fed a new hunger for learning. Literacy spawned the Renaissance (1500–1700), a period of European expansion into the continents of Africa, Asia, and the Americas. Global exploration refined mapping and navigation, while imperial conquest decimated native populations through warfare and disease. Discoveries of new lands and species also spurred growth in the descriptive sciences, especially geography, geology, and biology. A buoyant verbal fluency stirred the language arts, epitomized in the writings of Shakespeare, Cervantes, and Molière. Colonial empires used their literacy to record events and claim land as property. Native cultures often regarded words as totemic: their oral chants and stories were prayers, repeated to bless earthly cycles. Such radically different uses of language also expressed conflicting views of nature. Europeans sought to own the earth, even as their sciences and arts revealed the immense biodiversity of wild, untouched land.

With the rise of natural science after 1700, literature began to express growing respect for nature, especially those aspects of it that were rare and varied. Optical devices peered into the heavens and the human body, while theorists and engineers created new branches of knowledge, publicized and marketed by print, commerce, and coffeehouse (Jardine, 1999). New forms of technology changed the economic value of natural resources. Land remained a source of food and energy, but wealth increasingly came from products and services. Cities expanded by drawing rural tenants from the countryside; new social classes formed around labor, management, and capital. An expanding, literate middle class called for political reforms, replacing monarchy with representative democracy. Revolutions in the Americas pulled masses of immigrants to the new Western nations, where open territory and cheap land began to transform agrarian life into republican independence. (As the world has grown tamer in recent decades, wilderness has come to have a higher value, as land existing for itself, rather than for human enterprise.)

The study of natural diversity advanced through what Kuhn (1967) has called changing paradigms, theories or conventions that promoted experimentation. Early naturalists described organisms with confusing and inconsistent local vernacular until Carolus Linnaeus compiled *Systema Naturae* (1734), using Latin nomenclature to assign names by genus and species. Latin was dead and thus fixed, and Linnaeus used social distinctions (kingdom, phylum, class, order, family) to create taxonomy, a systematic language that described the bounty and variety of nature. While literary authors from Jonathan Swift to Fenimore Cooper mocked scientists for obsessive categorizing, taxonomy became a consistent model for geology, archeology, and philology. Those sciences

declared that prehistoric changes in the earth and in language follow traceable lines of descent across long stretches of time. Such discoveries replaced mythic accounts of creation with rational studies of the unity and diversity of organic events.

Darwinism and Literature

The new sciences spawned a second age of exploration, 1750–1850, as voyagers from James Cook to Alexander von Humboldt surveyed the continents of Australia and the Americas. In their wake followed a generation of literary naturalists like Gilbert White, William Bartram, and John James Audubon, who drew field sketches and wrote evocative accounts of seasonal journeys through rural or remote lands. The expeditionary narratives of Peter Kalm or Meriwether Lewis and George Rogers Clark are read today as literature and history, for they verify the immense variety of species that led to theories of biodiversity. This tradition of gentleman amateur molded Charles Darwin, who spent a 5-year expedition on the *HMS Beagle*, examining patterns in geology and zoology along the coasts of South America and on Pacific islands. Darwin was one of the last major scientists to be an independent field naturalist, living on his own income. After 1870 science moved to the laboratory bench and university departments, a shift in professionalism that also affected writers, who became teachers and seekers of literary prizes (Jardine, 1996).

In his major works, *Voyage of the HMS Beagle* (1839), *The Origin of Species* (1859), and *The Descent of Man* (1871), Darwin argued that species evolve through the effects of heredity, variation, and natural selection. He had several predecessors in science, from Georges-Louis Leclerc Buffon, who recognized adaptation, to Alfred Russell Wallace, who anticipated and clarified several of Darwin's ideas about selection. The term "evolution" is quite ancient, going back to Latin *evolvere*, to unroll, and may describe inscriptive scrolls, the writings that physically expressed a gradual process of change. The Biblical account of creation (Genesis 1) frames a sequence of originating events, each a division (night from day, land from water, plant from animal) that measures the binary logic of doubling, branching, and splitting, all recurrent patterns in nature. Poetry, tragedy, and biography all depict similar sequences of choice and accident, selection and reproduction. Those lines of cause and effect link the Bible to Homer and Sophocles, and then to Shakespeare or Milton. A constant theme in Western literature is the relation of creator, man, and nature, as chains of interactive events lead to human survival or extinction.

Literary traditions emerged from worship and theology, while Darwin stated that evolution proceeds according to physical laws, without divine intervention, and that human beings did not arise separately from other species. Early confirmation of these views appeared in the research of the Austrian monk Gregor Mendel, whose experiments in hybridization found that reproduction is a process of encoding and transmitting genetic material. Despite the strong controversy these views aroused among people of faith, by the 1860s evolution and genetic science began to alter popular

ideas of nature and produce the first authors who consciously recognized biodiversity.

Two leaders in this movement were Henry David Thoreau (1817–1862) and George Perkins Marsh (1801–1882). Their books (*Walden*, *Cape Cod*, *The Maine Woods*, *Man and Nature*) often examine the physical environment of New England, a region of low economic value but rich biodiversity. A self-trained land surveyor, Thoreau spent several years studying landforms and seasons. After reading *The Origin of Species* in 1860, he wrote the first modern accounts of forest succession and the dispersal of seeds (Howarth, 1982). Marsh, a lawyer and diplomat, published early studies of erosion, blaming land clearance and overgrazing, and he argued vigorously that human beings must learn to control their destructive impact on nature.

Among later writers known as social Darwinists (chiefly Herbert Spencer, Walter Bagehot, and William Graham Sumner), application of evolutionary theory to human behavior produced racist theories of cultural history, favoring white and Nordic peoples over Mediterranean and African. This bias, based on fears of immigration by darker races toward the wealthier nations, slants the novels of Jack London, Frank Norris, and Theodore Dreiser. Later these voices were replaced by modernist writers like T. S. Eliot, Willa Cather, and Ernest Hemingway, who saw racial diversity as healthy and progressive, a human check on industrial monopolies that had lain waste to natural resources and open spaces. Cather explored these issues on the plains of Nebraska, while Hemingway examined waning biodiversity in several lands, from upper Michigan to the savanna of east Africa, where great forests and wild herds are steadily destroyed by human incursion.

Ecology and Industrialism

The concepts of ecology were slow to gain acceptance among biologists and thus entered literary culture at a later date. Ernst Haeckel, a German biologist and advocate of Darwin, coined the term “ecology” in 1869 to describe how organisms form alliances that shape their number and distribution. Based in part on Haeckel’s political socialism, his views also echoed rising concern that industrial growth in Germany, France, and England had begun to damage both physical environments and public health (Bowler, 1994).

A vivid picture of decline lay in the western United States, where rapid agrarian settlement after the Civil War destroyed native tribes, bison, and grasslands in a few decades. The conservation movement of 1870–1920 sought to stem those losses by creating public lands and parks for protection of natural resources. Yet in the popular arts, writers of dime novels and outlaw ballads glorified “winning the West,” a form of historic triumphalism sanctioned by the theories of Frederick Jackson Turner (1893), who held that the frontier shaped fundamental American values of self-reliance and innovation. Later scholars note that the settlement process was destructive, as pioneers destroyed the very Eden they had sought (Mitchell, 1981).

With the experimental writings of James Joyce, Gertrude Stein, and William Faulkner, a modern critique of mass-industrial civilization began to emerge. Drawing on their perspectives as cultural outcasts (Irish Catholic, Jewish Lesbian, Southern Gentry), they mounted strong attacks on the

spiritual vacuity of urban life and, in Faulkner’s case, on the economic abuses that had sacked agrarian America. In his 14-novel saga about a fictional county in northern Mississippi, Faulkner assailed profiteering, an ideology that created slavery, miscegenation, one-crop farming, and soil erosion. He was the first modern novelist to comprehend ecological concepts, which gained attention in the 1930s from New Deal efforts to counter the wide-scale failure of capitalism.

The word “ecology” connotes a desire to coexist, if not in symbiosis, at least in a mix of competition and collaboration that marks the dynamics of a healthy, vigorous ecosystem. Darwin’s image of nature was “an entangled bank,” and throughout the twentieth century, ecologists created an interdisciplinary science that depicted nature as a web of interacting, interdependent forces that sustains itself – not as an unchanging constant, but as a vigorous dynamism sustained by frequent, patchy disturbances (Hagen, 1992).

Three writers who affirmed these principles, in sharply varying styles, were all Californians: Poet Robinson Jeffers, “hard-boiled” novelist Raymond Chandler, and John Steinbeck, a social novelist who was trained in marine biology and in the investigative methods of documentary journalism. In his literary works, especially *The Grapes of Wrath* (1939) and *The Sea of Cortez* (1941), Steinbeck built a vision of interlacing natural and cultural forces, locked in struggles that were shaped by biological conditions of production, consumption, and adaptation (Beegle, 1997).

Land Ethics and Environmentalism

After World War II, two writers emerged who were trained ecologists and willing to apply their influence to public policy. In their writings, Aldo Leopold and Rachel Carson issued firm warnings of environmental destruction by human means. Leopold’s *The Sand County Almanac* (1949) celebrates glaciated wetlands in Wisconsin, poor in economic value but rich in its diversity of habitats. His farm lies at the intersection of prairie, forest, and marsh, forming a mosaic of ecosystems that measure the “intricate tangle” of nature. Out of this vision, Leopold sketches the story of how he abandoned early conservationist ideas (a wildlife ranger, he was paid to kill wolves) for a preservationist vision he calls “the land ethic,” the sense that land deserves respectful protection as a vital element in the biotic community.

In *Silent Spring* (1962), biologist Rachel Carson intensified that sense of respect by analyzing the destructive force of chemical pesticides. In an incisive passage, she demonstrates how toxicity spreads through ground-water, a system of transport so invisible that it is easy to ignore. For her efforts, Carson was attacked by the petrochemical industry as hysterical and unscientific. But her logic and eloquence impressed the Kennedy administration, brought a ban on DDT and other pesticides, and eventually helped create the Environmental Protection Agency (Howarth, 1999).

Both Leopold and Carson saw that human values are formed by ideas of land, seeing that property is also a shared earth. Their books brought attention to emerging “green” political movements of the late twentieth century, from which two different land ethics developed: landscape, shaped by people

and inflected by aesthetic beauty, and land use, focused on food and energy extraction and marked by utilitarian security. Although often in conflict, the two ethics also reflect agreement that human identity rests on a sense of place, while alienation is feeling displaced, homeless, or unlanded (Spirm, 1999).

Natural Rights and Animal Fables

The perception that land deserves ethical regard soon led to extending rights to nonhuman species, both plant and animal, granting them value and respect while seeking to conserve their populations. Herman Melville's epic novel *Moby-Dick* (1851) anticipates this generosity, expressed in an iconoclastic rhetoric that denounces whaling. The cause of animal rights began with nineteenth-century reformers, who sought protection for religious dissenters, children, women, Indians, slaves, and other powerless groups. These figures came to be seen not as "lower" orders, but creatures having what Darwin called "the mutual affinities of organic beings." That phrase, the title of his penultimate chapter in *Origin of Species*, delivers his belief that humans are descended from all the creatures that have existed and still share the earth.

This theme enters literature in many animal tales written for young readers, from Anna Sewall's *Black Beauty* (1887) to E. B. White's *Stuart Little* (1945) and *Charlotte's Web* (1952). They descend from ancient beast and fairy tales, in which animals have the power to create language, before passing it on to humans. Such stories describe how things came into being, and they still have great attraction for writers drawn to environmental themes (Flynn, 1999). A contemporary example is David Quinn's novel *Ishmael* (1991), a series of dialogues between man and ape, in which the ape explains history as a conflict between Takers and Leavers, identified by their divergent approaches to the natural world. Takers dominate resources and evolve into modern urbanized man; Leavers are indigenous tribes who lead subsistence lives and eventually vanish.

While such accounts are fantastic, they also urge readers to think of animals, water, soil, rocks, and food as more than commodities. The cultural information provided in literary texts clarifies that natural objects result from processes, including the moral and ethical choices made by humans. As such choices recur in history, the value of a creature or a place changes: once the sea was thought to contain monsters, later it became a therapeutic place to bathe and sun; now it is emptying of fish and clogged with sewage (Hendrickson, 1984). Formerly the forest world was seen as profane and lawless, the home of pagans; now it is sacred, a haven for rest and retreat (Harrison, 1992).

Ecocriticism and Biodiversity

Scientists are now warning that a global environmental crisis will be the future outcome of several current trends: human overpopulation, the rise of carbon dioxide emissions, atmospheric warming, and the loss of biodiversity. These dangers transpire across vast frames of time and space that are difficult for nonscientists to imagine. A crisis that occurs in a locality,

such as flood or earthquake, is understandable, but one that works over a longer period and through evolutionary selection is invisible to most eyes.

Because its domain is virtual or imaginative, literature helps its readers to envision what they will never directly experience. Yet many variables also affect the ability of literature to depict the threat to biodiversity. A writer's personal involvement in a story will shape its tone, bringing nostalgia (Wallace Stegner) or urgency (Bill McKibben) to the subject matter. The work's form may illustrate its content, as when Peter Matthiessen shapes *The Snow Leopard* (1973) into a mountaineering ascent, using elevation to provoke meditations on higher metaphysical themes. An object described will take on the character of its subject, as when Annie Dillard expresses her notions of wildness through a weasel's alleged indifference to pain.

The work may also have a distinct cultural audience (John McPhee) or veer between standards of elite and popular reception (Edward Abbey). Some writers are sensitive to social and economic conditions (Edward Hoagland), others contrast regional and national concerns (Barry Lopez), still others attend to differences of race and gender (Sue Hubbell), or to the impact of other arts on literature (Anne Matthews). Environmental writing is often a mixed collection of genres; part scholarly research, part sermon-editorial, part whimsy and adventure. Similar manifestations affect the contemporary novels of Thomas Pynchon (*Gravity's Rainbow*, *Vineland*, *Mason*, and *Dixon*) and Don DeLillo (*White Noise*).

Because of the great variation in environmental writing, a new mode of reading called "ecocriticism" has emerged to establish interpretive standards. While not agreeing in all respects, ecocritics often seek to translate the specialized language of science, with its jargon and acronyms, into a common vernacular. Ecocritics are interpreters and bridge builders, looking for ways to connect the disciplines that university departments have long separated (Glotsfelty and Fromm, 1995). A few scientists, such as Wilson (1998), have written popular accounts of their environmental concerns, but mostly the public has turned to literary writers to gain insight into the causes and effects of waning biodiversity. At times these voices cannot agree about solutions, for the global biosphere is too intricate, too complex, and too unpredictable to describe readily, and some scientists believe that it will not be managed until it returns to preindustrial levels of stable composition (Peters, 1994).

Other ecologists have grave concerns about genetic erosion, through both species loss and also genetic engineering, which in the long term may produce fewer varieties of plants and animals (Karaim, 1999). The role of species biodiversity suggests that its purpose may be to provide redundancy, which has a stabilizing effect on whole communities and ecosystems. In the face of drastic environmental change, diversity may buffer ecosystems against the collapse of ecological function (Nudds, 1999).

If biodiversity works because variety protects a community against stress and disaster, then literary accounts of biodiversity must remain equally diverse and inventive for the sake of textual survival. A review of literary history suggests that the continuance of human life on earth will depend in part on what storytellers make of a changing world. The gift of

language brings insight, but also the wisdom to heed the silence that Annie Dillard calls “nature’s one remark.” The central question for human beings is not whether they will survive as a species, but whether the survivors will inherit a world worth sharing (Wilson, 1998).

Disaster and Mass-Media

In the first decade of the twenty-first century, several events eroded the optimism that once promoted hopes for sustained biodiversity. Consensus politics in the United States suffered from a series of blows: (1) the disputed election of a conservative president, George W. Bush; (2) attacks on 9/11/2001 by Islamic terrorists in New York and Washington, DC; (3) costly wars in Iraq and Afghanistan; and (4) a long, deep economic recession among developed nations. Hard times often create scapegoats, and in the second millennium, blame has shifted from corporations to government and environmentalists. Since the year 2000, Gallup polls of US public opinion have reflected declining trust in government, loss of economic confidence, and lower regard for environmental advocates (Dunlap, 2010).

At the same time, repeated instances of oil spills, earthquakes, storms, droughts, epidemics, and famine have brought increasing pressure on government and industry to provide fiscal and humanitarian relief from such disasters. A notorious event was the largest accidental marine oil spill in history, known as the *Deepwater Horizon* blowout of April–September, 2010, which caused immense damage to marine and wetland habitat in the Gulf of Mexico. The offending company, BP, acknowledged fault and paid for cleanup and reparations, then continued profitable operations in some 80 countries around the world. Whether the causes are natural or human, citizens expect immediate response, even while fiercely resisting new taxes and programs of assistance (Button, 2010).

This political turmoil has accompanied a profound revolution in mass-media, as the world of publishing and broadcasting has shifted from small nodes of power to a sprawling, intricately linked means of communication, the Internet. Originating in military research in the 1960s, the Internet went commercial in the 1990s and spurred the growth of personal computers and mobile devices, such as smart phones and tablets. Books, magazines, newspapers, radio, and film now circulate instantly in digital form. The effect on cultural production is clear: anyone may create a film, story, or picture and “publish” it on social media sites with little control by gate-keepers or public taste (Dennis and DeFleur, 2009).

For literature, the way ahead is uncertain. Ever since the 1800s, when writers left behind private patrons and embraced a reading public, literature has depended on a well-educated audience for whom reading is a leisure pastime. For two centuries, middle-class nuclear families sustained such popular literary genres as the novel, deriving from fiction a means of virtual experience. That social demography no longer prevails. Families are now two-income or single parent, commuting distances to work and having less time to read popular or serious books. The spread of cable television systems,

broadcasting on hundreds of channels, has decimated the once dominant print culture of book stores, reviewers, and readers (Striphas, 2010).

At the turn of the twenty-first century, writers of drama, film, poetry and fiction dealt very differently with questions of biodiversity. Theatrical treatments of the issue have been few, though street and community theater in emerging nations increasingly address issues such as water conservation and public health. In the realm of commercial film, the Australian documentary *Cane Toads* (1987) highlighted the perils of introduced species, as *Microcosmos* (1996), *Winged Migration* (2001), and *March of the Penguins* (2006) celebrated habitat preservation. Two films, in particular, shaped cultural and environmental-policy conversation on a global scale: Albert Gore’s *An Inconvenient Truth* (2006), on global climate change, and the pro-biodiversity epic *Avatar* (2009), which earned the highest box-office gross in history.

Between 1990 and 2010, a striking percentage of major literary prizes went to poets inspired by the natural world – Mary Oliver, Robert Hass, Paul Muldoon, W. S. Merwin. In postmodern fiction, by contrast, nature is often cast as a malicious or irrelevant Other. Technoculture, apocalypse, the posthuman, and the social construction of nature dominate the work of literary novelists from Cormac McCarthy (*The Road*) and Don DeLillo (*White Noise*) to David Foster Wallace (*Infinite Jest*) and Jonathan Franzen (*Freedom*). As tolerance for social and cultural variation increases, hostility toward the natural remains perhaps the last acceptable prejudice in the literary arena. One exception to this trend is the work of Dana Hand, whose prize-winning *Deep Creek* (2010) turns landscape and history into an exploration of the violence and racial hatred at the heart of frontier settlement.

As real human diversity fades under the onslaught of the commercial and the electronic, so does natural biodiversity. Those who work to preserve it heed an early warning, “In wildness is the preservation of the world.” Thoreau (2007) saw wildness as the mother of civilization, a rootstock that feeds the tree of life. His hope was that it could not vanish as long as we preserve literacy and write the stories that inform our long history of memory and imagination.

Glossary

Animism Belief in spiritual beings. The term is associated with the anthropology of E. B. Tylor, who described the origin of religion and primitive beliefs in terms of animism in *Primitive Culture* (1871). Tylor considered animism a minimum definition of religion and asserted that all religions, from the simplest to the most complex, involve some form of animism. From Latin *anima*, 'breath' or 'soul'.

Biocultural diversity The diversity of life in any of its manifestations, biological and cultural, which are interrelated (and likely coevolved) within a complex social-ecological adaptive system.

Ethics Codes that exert a palpable influence on human behavior. Embedded in worldviews, ethics provide models to emulate, goals to strive for, and norms by which to evaluate actual behavior.

Monotheism Belief in the unity of the Godhead, or in one God, as opposed to pantheism and polytheism.

Monotheism is a firm tenet of Islam and Judaism. Christianity, with its concept of Trinity, alone among the three monotheistic religions, dilutes monotheism. From Greek *mono*, 'one', and Greek *theos*, 'god'.

Pantheism The doctrine that identifies the universe with God. In Western thought, the term is associated with the Dutch philosopher Baruch Spinoza. His view represents an important criticism of the 'orthodox' view of a god whose reality is somehow external to the reality of the world. From Greek *pan*, 'all', and Greek *theos*, 'god'.

Religion Human recognition of superhuman controlling power, and especially of a personal God or gods entitled to

obedience and worship; the effect of such recognition on conduct or mental attitude.

Sacred natural sites Areas of land and water having special spiritual significance to people and communities.

Stewardship To hold something in trust for another, as in the Biblical (human) responsibility for husbanding God's gifts. In the present context, examples include Australian aboriginal 'looking after country', Andean Quechua 'caring for Mother Earth', and Canadian Ojibwa 'keeping the land'.

Traditional ecological knowledge A cumulative body of knowledge, practice, and belief, evolving by adaptive processes and handed down through generations by cultural transmission, about the relationship of living beings (including humans) with one another and with their environment. It is a subset of indigenous knowledge, which is local knowledge held by indigenous people or local knowledge unique to a given culture or society.

Traditional societies Groups in which knowledge, practice, and belief are handed down through generations largely by cultural transmission. Tradition itself evolves by adaptive processes, but not all tradition is necessarily adaptive.

Worldview The larger conceptual complex in which ethics are embedded. A.N. Whitehead called it the conceptual order, or one's general way of conceiving the universe, which supplies the concepts by which one's observations of nature are invariably interpreted. In general, worldviews limit and inspire human behavior, shape observations, and perceptions. Arnold Toynbee's *Weltanschauung*.

The Context: Religion for Encoding Ethics

Different groups of people in different parts of the world perceive and value sacredness differently. Religion is a general term that has become established in the Western world for a whole class of cultural codes and rituals. In the West, there often is little connection between a person's religion and environmental ethics. In many other societies, religion is part of a way of life as well as a worldview. For example, in Chinese there is no one word that translates as 'religion' in the Western sense. In some traditional societies, including many Amerindian groups, religion, worldview, and environmental ethics and practice are inseparable. It is appropriate, therefore, to define religion in its broader sense of 'human recognition of superhuman controlling power', inclusive of both monotheistic and pantheistic traditions.

Religions provide a central organizing myth and include cultural symbols for a moral code. Conceived that way, religions can be thought to include a wider variety of beliefs, within the definition of a superhuman controlling power. For example, one can refer to the 'religion of the market'. Peter Timmerman

uses the term 'econotheism' as the adoption of market economics "to bring the rest of the earth under new management". Econotheism, argues Timmerman, "contains within it all the elements of a religion: a priesthood, scriptures, catechisms (Econ 100 textbooks), an explanation of happiness and misery, a way to get to heaven, and a core model of the human". Eugene Anderson (1996) holds that religion is best regarded as something providing an emotionally powerful way to 'sell' a moral code. The content of the moral code is negotiable and variable; it is not in itself a part of the religion. One can have a moral code without a religion, as in secular humanism, but at the risk of losing the emotional content supplied by religion.

Religion has not been a particularly popular topic among those involved in biodiversity conservation. The index of the 1140-page *Global Biodiversity Assessment* of 1997 contains a grand total of only two minor entries on religion. One problem with religion is that it has often been bent to serve all possible ends, including those destructive of biodiversity and cultural diversity. The role of religion in biodiversity conservation, and more generally in environmental ethics, is controversial. However, in more recent years, the profile of

religion, as relevant to environmental sustainability, has increased. Two volumes (Taylor, 2005; Jenkins, 2010) provide details on the roles of various religious traditions, along with a journal devoted to this area (*Journal of the Study of Religion, Nature & Culture*). As well, a number of volumes examine spiritual traditions and sacredness in various cultures (Posey, 1999; Turner, 2005; Shaw and Francis, 2008; Berkes, 2012; Verschuuren et al., 2010).

There are several cautions in interpreting the discussion on religion and biodiversity. First, generalizations are always risky. As Donald Worster (1988) put it in *The Ends of the Earth*, “not a few scholars have fallen into the trap of speaking of ‘the Buddhist view of nature’ or ‘the Christian view’ or ‘the American Indian view’, as though people in those cultures were all simple-minded, uncomplicated, unanimous, and totally lacking in ambivalence. Every culture, we should assume, has within it a range of perceptions and values, and no culture has ever really wanted to live in total harmony with its surroundings”.

Second, there is invariably a gap between ‘the ideal’ and ‘the actual’ in making sense of how societies deal with biodiversity. Ethics do not describe how people actually behave but rather set out how people *ought* to behave. There often is a discrepancy between belief and practice. Some scholars argue that one could spend too much time on values and beliefs, neglecting to examine behavior or the actual effects of these values on human practices regarding the environment. The field of environmental history studies the historical record of changes in the landscape as a way of evaluating the actual effects of the belief-and-practice complex of a culture.

A third caution is the intangible nature of traditions and their record in the literature. Not only do traditions change and adapt all the time, but the literature is based largely on outsiders’ accounts of various religious traditions, especially those that do not have a written record. Since traditional societies are, by definition, those cultures in which much knowledge is transmitted orally, available documentation on such groups is almost always suspect. This is because insiders do not normally record their teachings in writing, and outsiders do not always interpret these teachings correctly and tend to add their own interpretations.

Monotheistic Traditions

Debates Over the Judeo-Christian Tradition

The controversy about environmental values in Christianity and Judaism has centered on the appropriate interpretation of

the relationship between God, ‘man’, and nature as set out in the Book of Genesis 1:26–28:

“26 And God said, Let us make man in our image, after our likeness: and let them have dominion over the fish of the sea, and over the fowl of the air, and over the cattle, and over all the earth, and over every creeping thing that creepeth upon the earth.

27 So God created man in His own image, in the image of God created He him; male and female created He them.

28 And God blessed them, and God said unto them, Be fruitful, and multiply, and replenish the earth, and subdue it: and have dominion over the fish of the sea, and over the fowl of the air, and over every living thing that moveth upon the earth”.

There are two widely held interpretations of the relationships implied by these quotations. The ‘mastery’ interpretation is that Genesis gives humans a unique status among the species by virtue of creation in the image of God, and awards humans a God-given right to exploit nature without moral restraint, except where it affects human welfare. God, according to this view, seems to have intended humans to be his viceroy on earth. Humans are to the rest of earth’s species as God is to humans. Humans are given dominion over the earth, and are expressly asked to subdue (Hebrew *kabas*, stamp down) the earth, as if nature needed humans to put it in order.

The ‘stewardship’ interpretation also relies on the verses above, as well as others before and after it, and emphasizes responsibility. Since humans are created in the image of God, they have not only rights and privileges but also special duties and responsibilities. Foremost among these is the human duty to rule the dominion of nature wisely. To degrade nature and destroy God’s other species would violate the trust God has placed in his viceroy. Thus, far from giving a free hand to exploit and degrade nature, according to this view, God expects humans to exercise stewardship in the wise use of nature.

The Assisi Declarations (1986) reproduced here are excerpts from five of the addresses by religious leaders to their own faithful in the Buddhist, Christian, Hindu, Jewish, and Moslem worlds. The Declarations were the highlight of an interfaith ceremony at the World Wildlife Fund’s 25th anniversary celebrations. The three monotheistic traditions represented in **Box 1**, **Box 2**, and **Box 3** (Christian, Jewish, and Moslem, respectively) make it clear that all three strongly support the stewardship interpretation of Genesis. It should be noted that Islam’s holy book, the Qur’an, is similar in content to the Old Testament, and gives humans dominion over nature, but at the same time, as the declaration notes, vests in them trusteeship and accountability.

Box 1 Excerpts from the five declarations of assisi: The christian declaration by Father Lanfranco serrini

Because of the responsibilities which flow from his dual citizenship, man's dominion cannot be understood as license to abuse, spoil, squander or destroy what God has made to manifest his glory. That dominion cannot be anything else than a stewardship in symbiosis with all creatures. On the other hand, his self-mastery in symbiosis with creation must manifest the Lord's exclusive and absolute dominion over everything, over man and over his stewardship. At the risk of destroying himself, man may not reduce to chaos or disorder, or, worse still, destroy God's bountiful treasures. For St. Francis, work was a God-given grace to be exercised in that spirit of faith and devotion to which every temporal consideration must be subordinate: uncontrolled use of technology for immediate economic growth, with little or no consideration for the planet's resources and their possible renewal; disregard for just and peaceful relations among peoples; destruction of cultures and environments during war; ill-considered exploitation of natural resources by consumer-oriented societies; unmastered and unregulated urbanization; and, the exclusive preoccupation with the present without any regard for the future quality of life.

Box 2 Excerpts from the five declarations of assisi: The jewish declaration by Rabbi Arthur Hertzberg

The encounter of God and man in nature is conceived in Judaism as a seamless web, with man as the leader and custodian of the natural world. Even in the many centuries when Jews were most involved in their own immediate dangers and destiny, this universalist concern never withered... Now, when the whole world is in peril, when the environment is in danger of being poisoned, and various species, both plant and animal are becoming extinct, it is our Jewish responsibility to put the defence of the whole of nature at the very centre of our concern.

... Man was given dominion over nature, but he was commanded to behave towards the rest of creation with justice and compassion. Man lives, always, in tension between his power and the limits set by conscience.

Our ancestor Abraham inherited his passion for nature from Adam. The later rabbis never forgot it. Some 20 centuries ago they told the story of two men who were out on the water in a rowboat. Suddenly, one of them started to saw under his feet. He maintained that it was his right to do whatever he wished with the place which belonged to him. The other answered him that they were in the rowboat together – the hole that he was making would sink both of them (Vayikra Rabbah 4:6).

Box 3 Excerpts from the five declarations of assisi: The moslem declaration by Dr. Abdullah Omar Nasseef

Unity, trusteeship and accountability, that is *tawheed*, *khalifa* and *akhray*, the three central concepts of Islam, are also the pillars of the environmental ethics of Islam. They constitute the basic values taught by the Qur'an. It is these values which led Muhamad, the Prophet of Islam to say: "Whoever plants a tree and diligently looks after it until it matures and bears fruit is rewarded", and "If a Moslem plants a tree or sows a field and men and beasts and birds eat from it, all of it is charity on his part", and again "The world is green and beautiful and God has appointed you his stewards over it". Environmental consciousness is born when such values are adopted and become an intrinsic part of our mental and physical makeup. Moslems need to return to this nexus of values, this way of understanding themselves and their environment. The notions of unity, trusteeship and accountability should not be reduced to matters of personal piety; they must guide all aspects of their life and work. Shariah should not be relegated just to issues of crime and punishment, it must also become the vanguard for environmental legislation. We often say that Islam is a complete way of life, by which it is meant that our ethical systems provides the bearings for all our actions.

Searching for a New Religious Base for Environmental Ethics

The debates over the interpretations have been going on since the 1970s. Many environmentalists do not see monotheistic stewardship as a sufficient solution. The critics include the historian Lynn White Jr., who started the debate over Judeo-Christian environmental ethics with his classic 1967 paper in *Science*, 'The historical roots of our ecologic crisis'. According to White, Christianity is the most anthropocentric (human-centered) religion the world has ever seen, especially in its Western form. In pre-Christian times every tree, every spring, every stream, every hill had its own *genius loci*, its guardian spirit. These spirits were accessible to men, but were very unlike men; centaurs, fauns, and mermaids show their ambivalence. Before one cut a tree, mined a mountain, or dammed a brook, it was important to placate the spirit in charge of that particular situation, and to keep it placated. By destroying pagan animism, Christianity made it possible to exploit nature in a mood of indifference to the feelings of nature.

Since the roots of the environmental crisis "are so largely religious", White continues, "the remedy must also be essentially religious". He briefly entertains and then rejects Zen Buddhism as a solution: "Zen is as deeply conditioned by Asian history as Christianity is by the experience of the west, and I am dubious of its viability among us". Seeking instead an alternative Christian view, White proposes Saint Francis of Assisi as a patron saint for ecologists. "The key to an understanding of Francis is his belief in the virtue of humility – not merely for the individual but for man as a species. Francis tried to depose man from his monarchy over creation and set up a democracy of all of God's creatures".

White may be taken to recommend a Franciscan theology as the basis for a Christian environmental ethic. Others have provided other Christian theologies. For example, Rene Dubos in *A God Within* (1972) recommends St. Benedict, as the

Benedictines were the original environmental managers of Europe who drained swamps and made the countryside both productive and beautiful. The theologian John B. Cobb Jr., casts his net wider, beyond European cultures, in looking for a religious solution in *Is It Too Late? A Theology for Ecology*, and others have done the same (Levine, 1994; Wirzba, 2003).

Accepting White's (1967) view that Christianity is largely responsible for the environmental crisis, Cobb (1995) examines in particular American Indian and Chinese worldviews. He rejects the American Indian view because, he thinks, Indians did not respect human life sufficiently and because the Indian way of life cannot support the existing North American population. Turning to the Chinese tradition (represented by Taoism), Cobb argues that it was unable to prevent deforestation and other ecological ills. He concludes that it is more prudent for the West to fix the Western tradition than to find a non-Western alternative. Rejecting Francis as too radical (Saint Francis had also preached poverty to the Catholic Church!), Cobb finally opts for Albert Schweitzer's Christianity and his reverence-for-life ethic.

The historian Arnold Toynbee differs from the above-mentioned commentators in that he sees no fundamental problem in developing a new environmental ethic that can be integrated with Asian traditions. As a classically educated scholar, he sees a historical continuity from pantheistic traditions ('the original religion of all mankind') to the Greco-Roman religion and to Asian religions. At the western end of the Old World, this nature-worship, which is the original religion of all mankind, has been overlaid by an opaque veneer of Christianity and Islam. However, when a native of the monotheistic portion of the present-day World travels eastward beyond the easternmost limits of Islam, he finds himself in a living premonotheistic World, and, if he has had a Greek and Latin education, the religion of present-day East Asia will be more familiar to him.

Monotheism is exceptional among the religions of the world in its doctrine about subduing nature, says Toynbee. As enunciated in the Book of Genesis, monotheism has removed the sense of awe and, with it, the age-old restraint that was once an effective check on human greed. His analysis does not so much negate the stewardship interpretation as makes it irrelevant. The real solution to the crisis, in Toynbee's thinking, has to do with restoring a sense of sacred respect for the earth and its creatures; the remedy lies in reverting from a worldview of monotheism to a worldview of pantheism.

Of course, the historical roots of the ecological crisis are not only found in the area of religion. A complex of social changes related to the Age of Enlightenment, the Industrial Era, and the commodification of nature has been implicated, as part of what Karl Polanyi (1944) calls the *Great Transformation*. A major factor, according to C.J. Glacken (1967) and others, is the Age of Enlightenment concept of an external environment analytically separate from humans. Many scholars, including Gregory Bateson, hold that this separation is the basis of the Cartesian dualism of mind versus matter, and hence humans versus the environment. Searching for a way to bridge the dualism, Bateson became 'aware gradually that the unity of nature ... might only be comprehensible through the kind of metaphors familiar from religion ... an integrative dimension of experience that he called the sacred' (Bateson and Bateson, 1987, p. 2).

There is no agreement among experts regarding the relative importance of the emergence of monotheistic traditions in the West versus that of the Enlightenment philosophy and the great transformation many centuries later. The change in values accompanying the former was no doubt complemented and reinforced by the latter. Together, these two waves of

change left the Western world with a fundamentally altered relationship with nature. The 'disenchantment of the world' in modern society may be seen as a loss of spiritual enchantment with life. For premonotheistic people, by contrast, nature was not just a treasure trove of natural resources; nature was a goddess and the whole of the environment was sacred.

Asian Traditions

The religious traditions of South Asia and East Asia, with their many gods and nondominant relationship to nature, are similar in many ways to the premonotheistic traditions of Europe, and fundamentally different from the monotheistic tradition, as Toynbee would argue. "Confucianism and Taoism and Shinto, like the pre-Christian Greek cults of the corn-goddess Demeter (Ceres in Latin) and the wine-god Dionysus, counsel man to respect nature even when he is applying his human science to coax nature into bestowing her bounty on man". Elements of this thinking can be seen in the Buddhist and Hindu declarations in Assisi. The statements "we should be wary of justifying the right of any species to survive solely on the basis of its usefulness to human beings" (Box 4) and "the divine is not exterior to creation, but expresses itself through natural phenomena" (Box 5) signal a worldview that is fundamentally different from the monotheistic one.

The influence of Hindu teachings can be traced in the environmental literature regarding species preservation and animal rights. The philosopher Arne Naess (1989) adopted the concepts of "identification" and "self-realization" from Hindu thought and used them as central ideas in Deep Ecology. Zen Buddhism (a form of Buddhism) is one of the few major Asian

Box 4 Excerpts from the five declarations of assisi: The buddhist declaration by the Venerable Lungrig Nmgyl

Buddhism is a religion of love, understanding and compassion and is committed towards the ideal of non-violence. As such it also attaches great importance towards wildlife and the protection of the environment on which every being in this world depends for survival. The underlying reason why beings other than humans need to be taken into account is that, like human beings, they too are sensitive to happiness and suffering. We should therefore be wary of justifying the right of any species to survive solely on the basis of its usefulness to human beings. We are told that history is a record of human society in the past. From existing sources there is evidence to suggest that for all their limitations, people in the past were aware of this need for harmony between human beings and nature. They loved the environment. They revered it as the source of life and well-being in the world. We regard our survival as an undeniable right; as coinhabitants of this planet, other species too have this right for survival. And since human beings as well as other non-human sentient beings depend upon the environment as the ultimate source of life and well-being, let us share the conviction that the conservation of the environment, the restoration of the imbalance caused by our negligence in the past, be implemented with courage and determination.

Box 5 Excerpts from the five declarations of assisi: The hindu declaration by Dr. Karan Singh

Not only in the Vedas, but in later scriptures such as the Upanishads, the Puranas and subsequent texts, the Hindu view-point on nature has been clearly enunciated. It is permeated by a reverence for life, and an awareness that the great forces of nature – the Earth, the sky, the air, the water and fire – as well as various orders of life including plants and trees, forests and animals, are all bound to each other within the great rhythms of nature. The divine is not exterior to creation, but expresses itself through natural phenomena.

The Yajurveda lays down that "no person should kill animals helpful to all. Rather, by serving them, one should attain happiness". This view was later developed by the great Jain Tirthankara, Lord Mahavira, who regenerated the ancient Jain faith that lives down to the present day. For the Jains, Ahimsa, or non-violence, is the greatest good, and on no account should life be taken. This philosophy was emphasized more recently by Mahatma Gandhi, who always spoke of the importance of Ahimsa and looked upon the cow as a symbol of the benign element in animal life. All this strengthens the attitude of reverence for all life including animals and insects. The Hindu tradition of reverence for nature and all forms of life, vegetable or animal, represents a powerful tradition which needs to be renurtured and reapplied in our contemporary context. India, the population of which is over 80% Hindu, has in recent years taken a special interest in conservation.

religions to put firm roots in contemporary Western culture through the writings of D. T. Suzuki, Alan Watts, Peter Timmerman, and the poet Gary Snyder. However, “pop Zen” or “West Coast Zen”, as Callicott and Ames (1989) call it, has been used to reinforce selfish individualism already endemic in Western culture, instead of the self-discipline, simplicity, and enlightenment of true Zen.

Buddhism has also influenced some environmental writing. The most radical chapter in E. F. Schumacher’s (1973) *Small Is Beautiful* is entitled “Buddhist economics”. The West is rich in technological and economic means, Schumacher points out, but it has little clue about the ends that are most appropriate for the use of those means. Buddhist economics proposes the solution that appropriate means should be used to achieve appropriate ends. The discovery of these appropriate ends, in turn, can be guided through our place as caretakers of the world around us, and the appropriate means will then become obvious.

Taoism, one of the Chinese religious traditions, considers nature through the concept of Tao, the way, and emphasizes living in harmony with nature, of “flowing with nature”. Taoism has influenced Western culture and environmental thinking through such books as *The Tao of Physics* by Fritjof Capra (1975). In a Taoist story told by Timmerman, a philosopher falls asleep and dreams that he is a butterfly. From that moment on, he is never sure if he is a philosopher dreaming that he is a butterfly, or a butterfly dreaming that he is a philosopher. In Taoist thinking, the crucial point is that there is no right answer: the moment an answer is attempted, the original symmetry is broken and one crystallizes out as a philosopher or a butterfly—but not both. Capra, a physicist, argues that quantum physics works in much the same way as electrons move out of a probability sphere into determined existence.

Romantic notions of Asian religions are debunked by the geographer Yi-Fu Tuan (1974), who pointed out the discrepancies between attitude and behavior. “Western humanists commonly show bias in favor of Taoist and Buddhist traditions”, says Tuan. But the people of China, through their long history, have transformed and degraded the landscape in a major way. Specifically, Taoism, with its vaguely anti-urban and anti-humanistic stance, according to Tuan, represents little more than a hermit’s point of view in the larger scheme of environmental destruction. Tuan’s exposition of episode after episode of land abuse by the ancient Chinese, long before they

were influenced by the West, leads to the conclusion that Chinese religions are unlikely to provide a solution for all. However, this is not to deny that there existed a tradition of natural philosophy in China consistent with contemporary ecological ideals. Rather, Tuan’s critique points out that there often exist “glaring contradictions of professed ideal and actual practice”.

Pantheistic Traditions

Traditional Peoples, Indigenous Knowledge

Some traditional societies retain elements of pantheism, the ‘original religion’ of all humankind. In these societies, religion, worldview, and environmental practice are often intertwined (Brown, 1953; Callicott, 1994). Religious sanctions may be invoked in two ways in direct support of biodiversity conservation: through the prohibition of areas or of species. ‘Sacred groves’ or sacred forests occur throughout the world, especially in India, Indonesia, South America, and parts of Africa (Ramakrishnan *et al.*, 1998). **Box 6** illustrates the nature of sacred groves in one African country. There has been increased attention given to examining the role of sacred natural areas in conservation, and specifically in biocultural diversity conservation (Maffi and Woodley, 2010). Even small sacred groves may be surprisingly effective in conserving biodiversity (Verschuuren *et al.*, 2010). In the case of species taboos (the word is borrowed from the Polynesian *tabu*), a study by Colding and Folke (1997) showed that about 30% of taboos identified worldwide prohibited the use of species that also happened to be listed as threatened by the IUCN *Red Data Book*.

Traditional worldviews may also help conserve biodiversity indirectly through the emotional involvement of people with their land and living things. This may entail, as in some American Indian traditions, a community-of-beings worldview in which animals and plants are considered persons—not human persons but persons nonetheless. Land may also provide a strong sense of place or sense of identity for a social group, as seen with American Indians and Inuit, Southeast Asian indigenous peoples, and cultures in Oceania.

The report *Our Common Future* identified indigenous peoples as “the repositories of vast accumulations of traditional

Box 6 Sacred groves and traditional forest conservation in Nigeria

Among the Yoruba of southwestern Nigeria, there were a number of categories of traditional sacred forests, although these have fallen into disuse in recent years. According to the study, *Nigeria’s Threatened Environment* (1991), land was regularly set aside as hunting forests, religious groves, and isolation and quarantine forests, and to serve as the abode of fairies and spirits.

Igbo ode (hunting forest) was lands located at some distance from settlements and devoted to game. *Igbo egan* (high forest) was abandoned secondary forest. When put to use for game-hunting activities, it became *Igbo ode*. Lands were often named according to their wildlife inhabitants, e.g., *Igbo erin* (elephant forest) and *Igbo efon* (buffalo forest). Only brave hunters dared use such specialized forests.

Igbo oro (religious groves) were places set aside for religious worship of many of the elements of the physical environment. They were not extensive (usually less than a quarter of a hectare) and were uncultivated forests located on the borders of a settlement, in as many separate locations as there were families of the deities.

Igbo egbee (religious groves “land of sorrows”) were reserved forests for the burial of people whose deaths were considered mysterious. Such lands, isolated further away from settlements, were never put under cultivation in the past when diseases were rampant and sudden deaths were attributed to the anger of the gods. Only brave hunters dared enter such lands.

knowledge and experience that link humanity with its ancient origins" (World Commission on Environment and Development 1987, p. 12) and encouraged the use of this indigenous knowledge to develop new adaptive strategies for conservation. Who are these traditional societies and indigenous peoples? According to international criteria, four characteristics distinguish indigenous peoples from others. They are descendants of groups inhabiting an area prior to the arrival of other populations; they are politically not dominant; they are culturally different from the dominant population; and they identify themselves as indigenous.

Indigenous peoples are found in many parts of the world. Callicott's (1994) book on environmental ethics and religious traditions provides a representative survey of indigenous ethics from various parts of the world, with major sections entitled "Polynesian Paganism", "American Indian Land Wisdom" (with major cases of Lakota shamanism and Ojibwa totemism), "South American Eco-eroticism" (cases of Tukano systems theory and Kayapo agro-ecology), "African Bio-communitarianism" (cases of Yoruba anthropo-theology and San etiquette of freedom), and "Australian Aboriginal Conservators".

The globalization of Western culture has meant, among other things, the globalization of Western modes of production (e.g., monocultures) and resource conservation (expert-knows-best positivist science). Has ancient knowledge become irrelevant, or perhaps simply been swamped by Western science and practice? Conversely, are there useful lessons that can be learned from indigenous knowledge and practice? These are some of the central questions in a growing body of literature on traditional ecological knowledge.

The Context of Traditional Ecological Knowledge (Indigenous Knowledge)

Berkes (2012, p. 7) defines traditional ecological knowledge as a cumulative body of knowledge, practice, and belief, evolving by adaptive processes and handed down through generations by cultural transmission, about the relationship of living beings (including humans) with one another and with their environment. As a knowledge–practice–belief complex, traditional ecological knowledge includes the religious traditions of a society. It is both cumulative and dynamic, building on experience and adapting to changes. It is an attribute of societies with historical continuity in resource use on a particular land. By and large, these are nonindustrial or less technologically oriented societies, many of them indigenous or tribal, but not exclusively so. Traditional ecological knowledge is a subset of indigenous knowledge, generally defined as local knowledge held by indigenous peoples or local knowledge unique to a given culture or society.

Any discussion of traditional ecological knowledge and indigenous conservation needs to be qualified. The question of the relevance of traditional societies for biodiversity conservation is confounded by what has been called the 'noble savage' syndrome. On the one hand, there is the romantic, Rousseauian view of 'the primitive', intrinsically attuned to nature and somehow living 'in balance' with the environment. Such noble savages tend to become 'fallen angels' when they

come into contact with the dominant society. Lest they become a threat to the very ecosystem in which they live, they should continue to live as primitives, according to this view. On the other hand, there is the view that primitive people are not noble savages but tend to be ignorant and superstitious. Historically, they lived as biological populations at the mercy of natural forces and supernatural beliefs, not as organized communities with their own knowledge systems and ecologically adaptive practices. They had a tendency, even as primitive hunters, to trigger massive species extinctions, as in New Zealand, Polynesia, Madagascar, and perhaps the Americas and Australia.

As with all myths, there are elements of truth at the basis of these two views, and many people, including conservationists and indigenous people themselves, no doubt believe parts of one or more of these views. An alternative third view might start with the recognition that traditional ecological knowledge is not mere tradition but a set of adaptive responses that have evolved over time. All societies, prescientific and scientific, strive to make sense of how the world behaves, and to apply this knowledge to guide practice. Because people were dependent for their survival on resources in their immediate environments, there were strong incentives for them to use resources sustainably. They could not mask this dependence with fossil fuel subsidies or capital markets in a globalized economy. Thus, the ability to nurture and sustain biodiversity was a selective pressure on these societies. That is, there was a survival value in conserving and augmenting local biodiversity.

Prescientific, traditional systems of management have been the main ways by which societies have managed their natural resources for millennia. In many cases, the main reason we still have any biodiversity to speak about is because of these systems of management. Within this context, biodiversity conservation is the indirect outcome, rather than the objective, of traditional practices, but the practices themselves had adaptive value – biodiversity conservation was often a matter of survival.

Such a probabilistic and evolutionary view clearly rejects the notion that all traditional people always manage resources well. What the literature suggests is that groups can make mistakes but can also learn from their mistakes. They are capable of responding to resource collapses and to environmental change, along the lines suggested in the books *Linking Social and Ecological Systems* (Berkes and Folke, 1998) and *Sacred Ecology* (Berkes, 2012). Detailed accounts of traditional ecological knowledge do not support the noble savage. What they do is something very different: They provide a documentation of extremely detailed, pragmatic, empirical knowledge, represented in religious traditions and rituals, bound up with an emotional tie to the land and living beings.

Conserving Biodiversity: Traditional 'Rules of Thumb'

How indigenous knowledge of nature and human social behavior is translated into resource use practices that tend to promote sustainable use of the biota and conservation of biodiversity is little known. Better known, many traditional people exhibit resource use restraints that promote

conservation. But knowledge, belief, and practice leading to restraint tend to be intermingled, making it difficult to trace linkages among them. Conservation researchers often ignore social restraints on grounds that they are not considered rational in our worldview, often involving beliefs in supernatural forces, for example, as in the case of taboos. To arrive at an appropriate set of social restraints is an order of magnitude more complicated than to employ knowledge of habitat preference and behavior for efficient hunting strategies. To implement a set of social restraints is complicated also because it requires continued cooperation of a large number of individuals.

The dealings of traditional societies with nature are often hedged by prescriptions as to what, when, and how much is to be left undisturbed. These prescriptions become part of a culture and are mediated by religious traditions. Indian ecologist Madhav Gadgil and colleagues (1993) identified four kinds of widely used 'rules of thumb' as social restraints leading to indigenous biodiversity conservation practice:

Provide Total Protection to some Biological Communities or Habitat Patches

These may include pools along river courses, sacred ponds, sacred mountains, meadows, and forests. For example, sacred groves were once widely protected from Africa to China, and in fact, throughout the Old World. In the tribal state of Mizoram in northeastern India, they continue to be protected even after conversion to Christianity. It is now called a 'safety forest', while the village woodlot from which regulated harvests are made is called the 'supply forest'. Ecological theory suggests that providing such absolute protection in 'refugia' can be a very effective way of ensuring persistence of biological populations.

Provide Total Protection to Certain Long-Lived (K-selected) Species

Trees of all species of the genus *Ficus* are protected in many parts of the Old World. It is notable that *Ficus* is considered a keystone genus significant to the conservation of overall biodiversity. Local people seem to be often aware of the importance of *Ficus* as affording food and shelter for a wide range of birds, bats, and primates, and it is not difficult to imagine that such understanding was converted into widespread protection of *Ficus* trees at some point in the distant past. Taboos with apparent functional significance may also be placed on some less obvious species within the ecological community. For example, some Amazon fish species considered important for folk medicine are taboo and are avoided as food.

Protect Critical Life History Stages

In south India, fruit bats may be hunted when foraging, but not at daytime roosts on trees that may be in the midst of villages. Many waders are hunted outside the breeding season, but not at heronaries, which may again be on trees lining village streets. Cree Indians of James Bay in the subarctic hunt Canada goose, a major subsistence resource, but rarely kill or even disturb nesting geese. The danger of overharvest and depletion of a population is clearly far greater if these vulnerable stages are hunted and the protection afforded to them seems to be a clear case of ecological prudence.

Mandate Local Stewards to Monitor and Oversee Resource Use

Traditional resource harvesting systems in diverse parts of the world rely on the leadership of a traditional expert to organize the harvest, control access, supervise local rules, and generally act as a 'steward'. This practice also ensures the proper use and transmission of knowledge. Further, in some societies, major events of resource harvest are carried out as a short-term, prescribed group effort. Thus, many tribal groups engage once a year in a large-scale communal hunt. Such a group exercise may also serve the purpose of assessing the status of prey populations and their habitat and may help to adjust resource harvest practices to sustain yields and conserve biodiversity.

Considering that contemporary scientific prescriptions for biodiversity conservation are, in effect, also 'rules of thumb', these traditional prescriptions add up to a reasonably good set of practices. Thus, traditional knowledge, with its time depth of observations, and an accumulated experience of learning-by-doing, can help us arrive at practical, locally tailored prescriptions for resource use relevant to conservation needs.

Ecosystem People, Local Knowledge, and Sacred Respect

Many practices used by indigenous people contribute to the conservation of biodiversity through the use of more varieties, species, and landscape patches than do modern agricultural food production systems (which tend to rely heavily on the monoculture of a few varieties). Several volumes illustrate this notion (Posey, 1999; Grim, 2001; Turner, 2005; Berkes, 2012). Gary Nabhan's (2000) work in Arizona and Mexico provides an illustration of biodiversity enhancement due to traditional multispecies agriculture, in this case, as compared to a protected area. Investigating two similar oases in the Sonoran Desert, Nabhan found 32 species of birds in the US Organ Pipe Cactus National Monument on the Arizona side of the desert. The other oasis, 50 km away on the Mexican side of the border and still being farmed in the traditional Papago style by a group of Indian villagers, supported 65 species. A possible explanation was that the farmed oasis provided greater diversity and amounts of food available for the birds, as compared to the protected oasis.

There is evidence that indigenous practices based on good local observations and natural history can provide the capability to respond to feedbacks from the environment and to ecosystem change. The book *Linking Social and Ecological Systems* documents examples of multiple-species management, resource rotation, succession management, landscape patchiness management, and other ways of responding to and managing pulses and ecological surprises (Berkes *et al.*, 2000). Even assuming that biodiversity conservation is the *indirect outcome* of these practices, for the most part, the amount of ecological understanding suggested by these practices is considerable. Social mechanisms behind these practices include adaptations for the generation, accumulation, and transmission of knowledge and the use of local institutions and rules for social regulation. Religious traditions are important for the cultural internalization of traditional practices and for the development of worldviews and cultural values appropriate for them.

Some traditional societies have ecosystem-like concepts. Ancient conceptualizations of ecosystems exist in several American Indian, Asia-Pacific, European, and African cultures. Among some indigenous peoples of the North American Subarctic, *land* is more than a physical landscape; it encompasses the living environment, including humans. For example, the term used by the Dene groups of the Canadian Western Subarctic, *ndé* (*ndeh*), is usually translated as *land* but its meaning is closer to *ecosystem* because it conveys a sense of relations of living and nonliving things on the land. However, it differs from the scientific concept of ecosystem in that *ndé* is based on the idea that everything in the environment has life and spirit (Berkes, 2012).

Table 1 provides a summary of traditional ecosystem-like concepts in which the unit of nature is often defined in terms of a physical boundary (such as a watershed) and living and nonliving elements are considered interlinked (references in Berkes, 2012). For example, among the Gitksan people of the Pacific Northwest, tribal chiefs describe their land boundaries as 'from mountain top to mountain top' and orient themselves by two directional axes within this watershed framework: vertically up and down from valley bottom to mountain top, and horizontally, upstream and downstream. Detailed land use maps of the kinship-based *house* groups (*wilps*) of the Gitksan show that there is a close correspondence between watershed areas and *wilps* or clusters of *wilps*. Clearly, these are not merely political boundaries but watershed-ecosystems-as-territories.

In Oceania there was a wealth of ecosystem-like concepts. Examples include the ancient Hawaiian *ahupua'a*, wedge-shaped land units controlled by local chiefs, encompassing entire valleys stretching from the top of mountains to the coast and shallow waters. The variations of the Hawaiian system may be found in the Yap *tabinau*, the Fijian *vanua*, and the Solomon Islands *puava*. The common point in each is that the term refers to an intimate association of a group of people with land, reef, and lagoon and all that grows on or in them. It is the 'personal ecosystem' of a specific group of people. In the Solomons, for example, a *puava* is a named territory consisting

of land and sea, and it includes all lands and resources associated with a kinship group.

These examples provide insights into what Raymond Dasmann (1988) calls ecosystem people – people who depend heavily on natural resources of their own localities, and hence develop a very detailed understanding of their environment, as well as a spiritual intimacy with the land. Such indigenous ecological understanding is different from that of the scientist. These traditional views tend to depict ecosystems not as lifeless, mechanical, and distinct from people, but as fully alive and encompassing humans. In some cases, traditional concepts of land also incorporate spirits of animals and other natural objects (as among the Dene of Northern Canada and Alaska), and spirits of human ancestors, as among some African groups and among the Australian aborigines (the concept of Dreamtime).

Conclusions

In monotheistic traditions, humans have dominion over the earth. They have a God-given right to subdue the earth, but they are also the stewards of God with responsibility to take care of the earth. By contrast, pantheistic traditions do not have a dominant relationship with nature. Asian religious traditions and pre-Christian European traditions also have a nondominant view of nature. The record of different religious traditions in conserving biodiversity is mixed. This is because human behavior is conditioned not only by religious beliefs but also by many other forces and because both culture and science evolve over time (Capra, 1996).

Traditional knowledge–practice–belief systems, tapping the wisdom of many traditional cultures with pantheistic traditions, offers a number of lessons. These systems are characterized by a similarity of concepts of nature, in which humans are part of nature. As well, these knowledge systems are characterized by similarity in design. An example is shifting cultivation, developed apparently independently, by tropical forest peoples in Africa, South America, South Asia, and New Guinea. At the same time, traditional knowledge systems are characterized by a remarkable diversity in practice, even in adjacent areas. For example, taboos used in the social control of resources in Oceania can vary greatly from one island to another, and even from one part of an island to another. Such diversity in resource use practice contrasts with the relatively uniform conservation prescriptions of government agencies, and highlights the need for conceptual pluralism.

One important lesson from traditional ecological knowledge is that values and beliefs are important in encoding ethics, including the ethics of conservation. As Rappoport (1984) and Anderson (1996) point out, the use of emotionally powerful cultural symbols is important to develop and enforce a moral code. If this is true, the incorporation of values and beliefs into biodiversity conservation efforts is more likely to succeed than the use of purely scientific arguments or purely economic incentives.

A number of contemporary concepts appear to be exploring the combination of emotions and ideas that may help restore a sense of sacred respect. They include deep ecology (Naess, 1989), the biophilia hypothesis (love of living beings)

Table 1 Examples of traditional applications of the ecosystem view

System	Country/region
Watershed management of salmon rivers and associated hunting and gathering areas by tribal groups	American Indians of the Pacific Northwest
Delta and lagoon management for fish culture (<i>tambak</i> in Java), and the integrated cultivation of rice and fish	South and Southeast Asia
<i>Vanua</i> (in Fiji), a named area of land and sea, seen as an integrated whole with its human occupants	Oceania, including Fiji, Solomon Islands, and ancient Hawaii
Family groups claiming individual watersheds (<i>iworu</i>) as their domain for hunting, fishing, and gathering	The Ainu of northern Japan
Integrated floodplain management (<i>dina</i>) in which resource areas are shared by social groups through reciprocal access arrangements	Mali, Africa

(Kellert and Wilson, 1993), bioregionalism (with its combination of local self-reliance and sense of belonging), the related notion of 'sense of place' (Tuan, 1974), and the Gaia hypothesis which is the contemporary version of the Mother Earth idea. Each provides an approach to the understanding of reciprocal ties that bind humans with the natural world, and these ties invariably have a spiritual or religious aspect.

Social and Cultural Factors

Glossary

Adaptation Any behavioral pattern that makes a human or a cultural group more fit to survive and reproduce in comparison with other individuals or cultures.

Carrying capacity The maximum population that can be sustained indefinitely in a given area without changing the ecosystem in ways that will eventually reduce the sustainable population. This balance between population and resources is a dynamic one that involves changes in technology and other factors.

Community A social unit consisting of members who are in direct interaction with each other and who have a collective identity, however defined. Relationships in such a group are principally primary rather than secondary in nature, and conformity to group norms is achieved mainly by peer pressure.

Culture All capabilities and habits acquired by people as members of society.

Indigenous peoples Those groups of human beings who share and preserve direct, everyday connections to their distinguishable distinctive cultural roots (even though they may have willingly migrated or been forcefully moved from their homelands, including moves to cities). These indigenous peoples consciously or unconsciously draw on specific knowledge and strategies developed and tested by past generations to address current problems. Cultural

traditions emerge and are maintained in a dynamic process of creative invention and reinvention, as well as borrowing and adaptation from other subgroups and cultures.

Language A system of conventional spoken or written symbols that enable human beings to communicate as members of a social group and participants in its culture.

Management The efforts of humans to select, plan, organize, and implement programs designed to achieve specified goals; activities can range from protective measures to ensure that human influences on natural resources are minimized to greater interventions required to maintain diversity, install facilities, control populations, and eliminate unwanted elements.

Myth A story, usually of unspecified origin and at least partially traditional, that ostensibly relates actual events to explain some practice, belief, institution, or natural phenomenon and that is frequently associated with religious beliefs; myths provide models for human behavior and often emphasize behaviors that support conservation of biodiversity.

Religion The relationship between people and that which they regard as holy, often in supernatural terms. Religions include a wide range of ceremonies and ritual practices aimed at supporting the moral and ethical values of a society and maintaining natural or built sacred spaces where such ceremonies and practices can take place.

Religion and Biodiversity

Religions order the spiritual and physical relationships of people with other humans and with their environment. Approaches to conserving biodiversity that are based on cultural and religious values are often much more sustainable than those based only on legislation or regulation. While religions offer important guidance on the relationship between people and the rest of biodiversity, all religions are characterized by a wide gap between their philosophy and the practices of the people who have accepted the philosophy.

Religion frequently has had the effect of preventing excess human demands from outstripping the environmental resources that are required to support them. For example, in Roman times, high priests dictated that the well-being of humanity depended on thousands of animals being sacrificed every year, thereby having the effect of keeping the size of herds within the carrying capacity of the grazing lands. More fundamentally, religions provide a complex holistic view of how to use natural resources, supporting this knowledge with an ethical perspective that is built on the implicit social contracts that enable communities to function.

All of the world's major religions are today sensitive to the importance of biodiversity, though of course their historical

writings do not use today's conservation vocabulary. The following is a brief summary of some major religious belief systems and how they relate to modern biodiversity concerns.

Animism is a term applied to a wide variety of beliefs that focus on numerous spiritual beings concerned with human affairs and capable of either helping or harming people. Animism is a view of the world found among many traditional peoples who conceptualize an intrinsic spiritual connection between humans and nature. This connection has been described by Harvard University biologist Edward O. Wilson as "biophilia," an innate human need for contact with a diversity of life-forms. For example, in the North American desert, the Yaqui Indians believe that close communication exists among the plants, animals, birds, fish, rocks, and springs that inhabit the Sonoran Desert. Many traditional approaches to conservation are supported by religious beliefs, often based on various kinds of animism that have the effect of fostering respect for plants and animals. In many parts of the world, people have established sacred sites on the basis of inherent spiritual or religious significance. Such sacred sites, based ultimately on animistic beliefs, are often sanctuaries for biodiversity. They may well survive substantial cultural changes; for example, the Parliament of Kenya (a very modern institution) voted in 1990 to protect all of the country's remaining

sacred forests, known as *kaya*. Many animistic systems of belief are accompanied by the idea of *taboo*, that which is forbidden; breaking a taboo can bring sanctions such as illness, social ostracism, or even death. Taboo often applies to certain sets of natural resources that are particularly vulnerable to over-exploitation. Animism is also often associated with *totemism*, a complex of ideas and practices based on the belief in a mystical relationship (often kinship) between people and certain animals or plants; these relationships often include reverential and genealogical relationships between social groups or individuals and the totems. Totems normally are associated with taboos of avoidance, so an Amazonian Indian hunter within a social group that has the peccary as a totem may be forbidden from hunting peccaries. Thus totemism also helps to restrict exploitation of harvestable resources.

Buddhism, with a total of about 300 million practitioners found in many Asian countries, teaches that a behavior has a natural relationship to its resulting consequences in the physical world. All Buddhist teachings and practice come under the heading of *Dharma*, which means truth and the path to truth. Based on the teachings of the Buddha, who lived in Nepal more than 2500 years ago, Buddhism teaches that people are responsible for their actions and go through a cycle of rebirths before finally reaching *nirvana*. Right actions lead to progress toward *nirvana* while negative actions, such as killing animals, lead to regression from that goal. Committed to the ideal of nonviolence, Buddhism also attaches great importance to wildlife and the protection of biodiversity (though of course not using such modern terms in its ancient teachings). Respect for life in the natural world is essential, and by living simply one can be in harmony with other creatures and learn to appreciate the interconnectedness of all that lives. This is not to claim that nature is unchanging; on the contrary, Buddhism recognizes change as the very essence of nature. The Buddha taught that all things are interrelated and do not have an autonomous existence, so the health of the whole is inseparably linked with the health of the parts and the health of the parts is inseparably linked with the whole.

Christianity, with some 1.6 billion members, is the dominant religion in Europe, sub-Saharan Africa, the Pacific, and the western hemisphere. It has numerous denominations, all based on the belief in a single all-powerful God who created nothing unnecessarily and omitted nothing that is necessary. Christians believe that Jesus Christ was the son of God and a great teacher whose message was that all of creation is the loving action of God, who continues to care for all aspects of existence. The very nature of biodiversity considered in itself, without regard to humanity's convenience or inconvenience, is considered to give glory to the Christian God. Christianity teaches in effect that humanity may not disorder biodiversity or destroy God's creations, at the risk of destroying itself; in the Holy Bible, Ecclesiastes 3:19 says: "For that which befalleth the sons of men befalleth beasts ... as the one dieth, so dieth the other ... a man hath no preeminence above a beast." Human acts of irresponsibility toward creatures are contrary to the divine wisdom, which sustains and gives purpose to the interdependent harmony of the universe. Modern Christian teachings are that humanity, both individually and collectively, should perceive the natural order as a sign and sacrament of God, recognizing that all creatures and objects have a

unique place in God's creation. However, Christianity also recognizes a special role of humanity within creation. The Holy Bible contains Christianity's main teachings. It provides strong support to the protection of natural resources, including passages mandating the preservation of fruit trees (Deuteronomy 20:19, Genesis 19:23–25), agricultural lands (Leviticus 25:2–4), and wildlife (Deuteronomy 22:6–7, Genesis 9). The Bible often refers to the impressive intelligence of wild creatures, such as in Jeremiah 8:7–8, Proverbs 6:6–8 and 30:24–28, Numbers 22:22–35, and Isaiah 1:3.

Hinduism, the dominant religion in India with about 700 million followers, teaches the all-encompassing sovereignty of the divine, manifesting itself in a graded scale of evolution. While the human race is currently at the top of the evolutionary pyramid, it is not seen as something apart from the earth and its biodiversity. Hinduism is permeated by a reverence for life and an awareness that the great forces of nature – earth, sky, air, water, and fire – as well as biodiversity are all bound together within the great rhythms of nature. Hindus recognize that all lives play their fixed roles and function together so that no link in the chain of life is lost. The divine is not exterior to creation but expresses itself through natural phenomena. Hindus consider at least some forests and groves as sacred and associate various plants and animals with gods and goddesses in the Hindu pantheon. The most important teachings of Hinduism are contained in the Bhagavad Gita, a dialogue between Sri Krishna and Arjuna, which has a clear description of ecology as a cycle of life dependent on everything from bacteria to birds. Like animists, Hindus believe that all plants and animals have souls, and that people must do penance even for killing plants and animals for food. Hinduism involves sacrifice, forms of ritual worship that are designed to protect life through reinvigorating the powers that sustain the world by securing cosmic stability and social order. Hindus recognize certain rivers and mountains as sacred, because they give and sustain life.

Islam, with about a billion adherents, is the dominant religion in North Africa, the Middle East, and many Asian countries. Its teachings are very similar to those of Christianity in relation to biodiversity. The entire universe is God's creation; Allah makes the waters flow on the earth, upholds the heaven, makes the rain fall, keeps the boundaries between day and night, creates all of biodiversity, and gives it the means to multiply. *Tawheed* is the principle of Oneness of Allah, teaching that "there is no God but God and Mohammed is His messenger." This testifies to the unity of all creation and the interlocking grid of the natural order of which people intrinsically are parts. The *Holy Koran* provides a set of principles that define the relationship of man to God and of God to the environment in its totality. However, humans are considered a very special creation because they alone have the power to reason and think, giving them the potential to do great good, or great harm. For Islam, the role of people on earth is that of a *khalifa*, or trustee of God, so humans are entrusted with the safekeeping of earth and its biodiversity. People are answerable for their actions, including maintaining the unity of Allah's creation, the integrity of the earth, and its biodiversity. The Islamic relationship to biodiversity is that each generation uses and makes the best use of biological resources, without compromising the interests of future generations. The Koran

says, "With it we have produced diverse pairs of plants each separate from the others. Eat (for yourselves) and pasture your cattle; verily, in this are signs for men endowed with understanding" (Sura 20 Aya 53). While humans have the right to utilize and subjugate natural resources, this involves a commitment to conserve them both quantitatively and qualitatively. In the Koran, God says, "There is not an animal (that lives) on the Earth, nor a being that flies on its wings, but (forms part of) communities like you" (Sura 13 Aya 15). Thus Islam looks upon biodiversity as an expression of God's wisdom and omnipotence and as support for human development. This leads to the necessity of conserving and developing biodiversity for its own sake as well as for the benefit of humans. And the Prophet Mohammed said, "There is a reward in doing good to every living thing." Such beliefs can lead to biodiversity being conserved. For example, in Pakistan, representatives of original tree species still persist in old Moslem graveyards, because of a taboo against cutting these trees. And the only surviving population of a freshwater turtle, *Trionyx nigricans*, survives in a sacred pond dedicated to a Moslem saint in Bangladesh.

Jainism is one of the oldest living religions, beginning in India at least 2800 years ago. Jains believe that all living beings have an individual soul (*Jiva*), which occupies the body until it dies, then leaves the body and immediately takes birth in another. Attaining nirvana and thereby terminating this cycle of birth and death is the goal of Jain practice, much like Buddhism. Jainism is based on the principle of *ahimsa* (nonviolence) toward human beings and all of nature. Jains teach that no human quality is more subtle than nonviolence and no virtue greater than reverence for life. While biodiversity often is affected negatively by people, the intention to harm is what makes an action violent, and without violent thought no violent action is recognized. Jain cosmology recognizes the fundamental natural phenomenon of symbiosis or mutual dependence, with all aspects of nature belonging together and bound in a physical as well as a metaphysical relationship – an ancient perspective that is reflected in modern ideas about biodiversity.

Judaism, which originated in the Middle East but whose 18 million practitioners today are thinly spread around the world, teaches that God created the world, making order out of primal chaos. The sun, the moon, the stars, plants, animals, and ultimately humanity were each created with a rightful and necessary place in the universe. The encounter of God and man in nature is conceived in Judaism as a seamless web with man as the leader and custodian of the natural world. Judaism maintains that the earth is the arena that God created for man, half beast and half angel, to prove that he could behave as a moral being. Judaism views God as the divine "Giver of the Torah," which sets out a series of ethical obligations including many relevant to biodiversity. It teaches that the relationship between man and nature is one of ownership, though limited by good sense; man was commanded to behave toward the rest of biodiversity with justice and compassion. But humanity inevitably lives in tension between its power and the limits set by conscience. The Bible contains much environmental wisdom, for example, allowing agricultural fields to go fallow one year out of seven (Leviticus 25:1–5). The Bible also warns that even in time of war, it is forbidden to destroy fruit-bearing trees of one's enemies (Deuteronomy 20:19).

Shinto is the system of indigenous religious beliefs and practices of Japan, first appearing in written form around 1400 years ago, after Buddhism had been introduced into Japan. Shinto is based on beliefs concerning the nature and attributes of *Kami*, sacred power, which is found in all individual things. Shinto temples are often established on sites that have particular spiritual integrity and force, often with large groves of trees (totaling nearly 120,000 ha in Japan). Shinto is based on numerous sacred texts, collectively known as Shinten. Shinto is strongly based in rural agricultural practices, involving various ceremonies and festivals that guide the relationship between people and nature.

Sikhism, a modern religion that began in India in the late fifteenth century, builds on the message of the oneness of a universe created by an Almighty God, who is master of all forms in the universe and the source of the birth, life, and death of all beings. God has created the natural beauty, which exists and can be found in all of biodiversity. Without his *hukum* (order) nothing exists, changes, or develops, but having brought the world into being, God sustains, nourishes, and protects it. Biodiversity exists under God's command and with God's grace. Sikhism teaches against a life of conspicuous consumption, emphasizing mastery over the self rather than mastery over nature. A major value of Sikhs is to be in harmony with the earth and all creation. Obviously, people are moving farther in the opposite direction, but Sikhs argue that the current instability of the natural system of the earth is a reflection of the instability and pain within humans.

Taoism has a history of more than 2500 years and has been one of the main components of Chinese traditional culture. *Tao* means simply "the way" and is the origin of everything. The Tao took form in the being of the Grandmother Goddess, who came to earth to enlighten humanity. In Taoism, everything is composed of two opposite forces known as *yin* and *yang*. When the two forces reach harmony, the energy of life is created. Taoism judges affluence by the number of different species; thus a society with healthy levels of biodiversity is affluent, while societies with declining biodiversity are themselves in decline. Chinese Taoism, as reflected in the *Tao Te Ching* (c. 600 BC), calls for people to have a noninterventionist role in the natural world.

These short descriptions indicate that virtually all religions are very sensitive to biodiversity concerns, essentially asserting the interdependence of all life-forms and the need to treat all life with respect. But this religious perspective has not always been sufficient to conserve biodiversity. The special role of humanity within Christianity has often resulted in over-exploitation of natural resources and alienation of land from people; the recognition of the Ganges as a river sacred to the Hindus has not prevented significant pollution and biodiversity loss at the hands of people; the unity maintained by balance advocated by Islam is today being replaced by environmental pressures that lead to disunity and imbalance; and the Tao noninterventionist perspective did not prevent the ancient Chinese from making profound changes to the land and water around them. Numerous indigenous cultures have been destroyed or fundamentally modified by missionaries from the major religions, who often are accompanied by technological innovations. But religions constantly evolve, and it is possible that a stronger religious response to

biodiversity loss will evolve as the concerns about such loss begin to affect people more profoundly.

Language and Biodiversity

This section draws from a contribution by Luisa Maffi. As an essential part of human cultures, languages provide the categories to conceive the natural and social world. A species of plant or animal that is important to a community gets named, and by learning that name, the people within the culture also learn what is vital to know in their natural environment. Thus language helps to organize the world and frees energy for other tasks, using words like pegs on which to hang the meanings stored in the storehouse of the human mind and providing a framework that binds together the details into a meaningful whole. Words for objects and phenomena help us learn the connotations, associations, emotions, and value judgments of a culture. Thus knowledge, beliefs, and values are linguistically encoded, thereby helping to promote a diversity of adaptive ideas and support various forms of biodiversity.

Many scientists argue that the preservation of the world's linguistic diversity (totaling more than 6000 languages) and the distinct forms of local knowledge that local languages encode must be incorporated as an essential goal in bioculturally oriented diversity conservation programs. Indeed, the diversity of human languages may be the best available indicator of human cultural diversity.

Many indigenous peoples believe that the external reality or environment is no different than the description of this reality or environment in a linguistic ecology. Variation in humans is adaptive, and language helps to support cultural diversity in humans. Human culture is a powerful adaptation tool and language both enables and conveys much cultural behavior.

Many countries with high biodiversity also have high cultural diversity, as indicated by their large number of languages. Languages have multiplied and thrived in places where natural selection has produced a rich variety of landscapes, animals, and plants. Researchers have found that linguistic diversity in sixteenth century North America was greatest in areas with the greatest diversity of habitats, irrespective of the latitude. Ten of the 12 "megadiversity countries" are among the top 25 countries for endemic languages. This correlation between biodiversity and linguistic diversity may have been fostered by a process of coevolution of small-scale human groups with their local ecosystems, in which humans interacted closely with the environment, modified it as they adapted to it, and acquired intimate knowledge of it. This knowledge was encoded and transmitted through language, supporting the contention of some linguists that life in a particular human environment depends on the ability of people to talk about it.

In many parts of the world, anthropologists have found a strong correlation between biodiversity, linguistic diversity, and ethnobiological knowledge. More generally, landscapes are anthropogenic not only in the sense that they are physically modified by human intervention, but also because they are symbolically brought into the sphere of human communication by language – by the words, expressions, stories,

legends, and songs that encode and convey human relationships with the environment and that inscribe the history of those relationships onto the land. When people name places, they are identifying where things happen within the local environment, thus providing an entry in a mental encyclopedia that helps to describe the ecological niche occupied by the local peoples.

For example, certain American Indian groups in the Pacific Northwest have an extensive vocabulary for talking about salmon and other fish, vegetation, streams, and trails, along with extensive development of grammatical devices that express the direction, distances, and relative positionings of these valuable features. Thus language helps to enable these seminomadic hunter-gatherers to be very clear about where they were and where they needed to go to find food and other necessities. Many cultures in the far north have numerous names for various types of snow, and pastoral peoples have detailed terms for various types of livestock. The richness of language thereby reflects the many ways people relate to their environment.

Indigenous Peoples, Resource Management, and Biodiversity

Humans earn a living from the earth and its biodiversity in four main ways: hunting and gathering, pastoralism, shifting cultivation, and permanent agriculture. Only the latter is sufficiently productive to enable large cities to flourish, and the very high productivity enabled by irrigation may have been needed for civilization. Historical evidence indicates that traditional activities related to agriculture, fishing, and livestock husbandry sometimes have led to sustainable systems that were in the self-interest of the people involved, at least at their current level of population and technology. But all four forms of using biological resources carry with them the dangers of overexploitation. Broadly speaking, the combination of technology and population growth potential requires human cultures to develop effective ways of living in a sort of balance with the resources available with a given technology. The extinction of numerous cultures over time indicates how frequently the limits have been exceeded. However, many cultures have developed belief systems and practices that served to limit overexploitation and to foster greater biodiversity (even if these benefits sometimes were unintended).

For most of our history as a species, humans were hunters and gatherers, living from harvesting a very wide range of plants and animals; a few such groups still survive today, usually where agriculture is impossible or impractical. Hunter-gatherers were usually nomadic and fit ecologically into their habitat in much the same way as other omnivorous species. An important discovery that interrupted this presumed harmony and may have had major ecological impacts on biodiversity was the deliberate use of fire for driving game and clearing forest. This cultural activity produced major modification in vegetation patterns and fauna distribution in at least some regions. The invention and use of spears, bows and arrows, harpoons, and nets also must have affected the interrelationships between human beings and populations of other animal species. The effects of culture on humans themselves in

the hunter-gatherer phase included impacts on techniques of food gathering, especially hunting. Nevertheless, with the exception of the use of fire in some situations, it is difficult to accurately determine the impacts on biodiversity of these changes.

Given the very great variability in approaches to resource management taken by various groups of hunting peoples, it is not surprising that various hypotheses have been developed to explain why some groups of indigenous peoples appear to have been able to live in better balance with their resources than other groups. A common observation is that ethnic groups that have lived in an area for extensive periods of time and appear most dependent on their locally available resources are most likely to have developed sustainable forms of resource use. Many of the population processes that link human hunters and their prey occur over timescales that elude both ethnographic and archeological field-work. The critical factor is the distinctive features of the foraging economy and their outcomes for resource population ecology, as a matter of behavior with practical consequences.

Fishing is a specialized form of hunting and gathering. People who depend primarily on fish for their protein typically have developed both technology and management techniques to ensure sustainable yields. For example, Amazonian Indians may avoid certain parts of the river during breeding seasons; eastern Indonesian fishermen have complex systems of taboos, known as *sasi*, which control how and when the fishing grounds are to be used; and Polynesian fishermen had various taboos that served the function of managing their fisheries.

The development of domestication of plants and animals about 10,000 years ago marked the beginning of an entirely new era in the interplay between human society and biological systems. The controlled breeding of plants and animals, using a small sample of the world's biodiversity, established a more reliable and expandable resource base than subsistence hunting and gathering, enabling humans to reduce substantially the space required for sustaining each individual and allowing the human population to increase. All early farming activities consisted of redistributing plant and animal species in a given area by deliberately increasing the local concentrations of the species humans valued and decreasing concentrations of species that competed with the favored ones. In terms of biodiversity, the selective breeding of species also expanded the range of human impact from habitats and species to genes. The 40 or so species of animals that have been domesticated have often greatly increased their genetic diversity, range, and populations due to human management, as have the 100 or so main domesticated plant species and the thousands of other plants selected for use as food, spice, medicine, decoration, and construction. But the gains for these species typically have been at the expense of other species which people found less easy to mold to their vision of the desirable.

Domestication of livestock apparently arose after domestication of plants and remains the most significant use of arid and semiarid lands by people. The dangers of overgrazing have led to many beliefs about human relationships, livestock management, and range management. For example, many Middle Eastern pastoralists had complex ways of sharing grazing lands, including the idea of *hema*, a traditional grazing

reserve. At least some species of trees typically are considered sacred by pastoral peoples and are not destroyed except in times of dire need; conservation of such vegetation thereby provides an emergency resource reserve (as well as conserving biodiversity).

Fallowing was the agricultural technique originally followed in most places; it remains a component of the shifting cultivation systems in many parts of Asia, Africa, and Latin America today. Such systems often use fire as a means of clearing the land, so they are sometimes called "slash-and-burn" systems. Such a system involves cultivating a plot of land – known as a "swidden" – for a few years and leaving it to develop into successional stages for a much longer period. This process creates a mosaic of vegetation, much of which is useful for foods, medicines, building materials, and other useful products (such as dyes, colorings, ceremonial objects, etc.). Many species of wildlife, including birds and terrestrial mammals, are attracted to the fallow swiddens because of their high productivity of nutritious vegetation. Furthermore, part of the land was often left out of cultivation. Thus in northeast Indian states like Manipur, as much as 10 to 30% of the land was permanently maintained under natural mature vegetation in the form of sacred groves. Historically, this would have ensured the persistence of almost all the natural elements of biodiversity, coupled with stimulation of overall productivity by favoring faster-growing early successional species in the patchwork of successional stages covering 70–90% of the land. Selection for adaptation to highly heterogeneous local environments also promoted considerable genetic variation in the cultivated species.

As an example of how shifting cultivation affects biodiversity in the Ecuadorian portion of the Amazon forest, Runa Indian swiddens resemble agroforestry systems rather than the slash and burn that merely results in temporary clearings in the forest canopy. Compared to unmanaged fallows, management actually increases species diversity in 5-year-old fallows. Between 14% and 35% of this enhanced species diversity is attributed to direct planting and production of secondary species. Thus Runa agroforestry can be seen as a low-intensity succession management system that alters forest composition and structure in the long term.

Among the most diverse of agricultural systems known are the home gardens in the humid tropics of tropical Asia, the result of long historical development of technology designed to meet the needs of local agricultural communities. In West Java, the typical home garden appears as a crowded assemblage of trees, shrubs, climbers, herbs, and creeping plants that are used for fruit, vegetables, starchy food crops, spices, ornamentals, medicines, fodder, fuel, and building material, and involve greater than a hundred species useful to people.

The Kantu of Kalimantan, Indonesia, plant at least 44 varieties in one area with an average of 17 per household. A gene pool of potatoes of some 3000 varieties representing eight species is traditionally under cultivation in the Andes. In Papua New Guinea, as many as 5000 varieties of sweet potato are under cultivation, with as many as 20 varieties being planted in a single garden. Thus indigenous peoples often maintain high biodiversity, at least among those species useful to them.

Traditional Belief Systems and Resource Management

The way of life of the world's tribal or indigenous peoples depends closely on biodiversity, often using cultural and religious beliefs to avoid disastrous overexploitation. Notions of sustainability of use are inherent in the value systems of many traditional societies, usually manifested in some notion of intergenerational equity. For example, the Iroquois tribe in North America would plan for the seventh generation when making their decisions, the life span, incidentally, of the dominant tree in their region. And the Koyukon Indians believe that future events will depend on the way people behave today and that the world can be nurtured by prudent use or harmed by unrestrained abuse; but equally important, the natural world will respond to gestures of respect given by those who recognize its sensitivity and awareness and humble themselves to its power. Plains Indians generally believed that their relations with other species were regulated by expectations and obligations similar to those that governed relations between kin or allies; such relations could vary from beneficial to harmful and could be mediated by ritual specialists.

In Colombia, the forests of the northwest Amazon basin harbor the world's most diverse array of plants and animals. This region is often considered part of the world's greatest remaining tropical wilderness. But the Tukano people who live there perceive their "wilderness" environment to be anthropogenic, transformed and structured in the past by the symbolic meaning their ancestors gave to resources and the knowledge they obtained about the plants and animals that enabled people to survive. Their forest is a system of resources in which the energy produced is directly proportional to the amount of energy it receives, a very modern perspective. They know that they cannot harvest more than the forest can produce, and they apply sophisticated knowledge of individual species and their uses. Their myths tell of animal species that were punished by the spirits for indulging in gluttony, boastfulness, improvidence, and aggressiveness. These myths serve as object lessons to human society, in which animals are metaphors for survival. By analyzing animal behavior, the Tukano find an order in the physical world within which human activities can be adjusted.

The restraints on harvesting may involve protection to keystone species that may support the persistence of a range of other species. Thus fig trees belonging to the genus *Ficus* are recognized as important sources of fleshy fruits available in seasons when no other species are producing such fruits in the tropical forest communities. *Ficus* thereby promote persistence of a number of insect, bird, bat, squirrel, and primate species for which they serve as a critical resource in a period of fruit shortage. All species of *Ficus* are even today to some extent protected as sacred trees through much of tropical Asia and Africa, where the local communities are aware of this ecological role. In other parts of the world, other species of useful trees may also be sacred, such as date palms in desert areas, baobab trees in Africa, palmyra in Brazil, and kapok among the Mayas.

Harvesting restraints also include protection of critical stages in the life history of species that are especially vulnerable to overharvest. Thus a nomadic hunting tribe of Western India has the tradition of releasing any pregnant does or fawns

of antelope or deer caught in their snares, and egrets, storks, herons, pelicans, ibises, and cormorants at their colonial nesting colonies are given immunity from hunting over most of India, although these birds are hunted in the nonbreeding season. In many Asian villages, fruit bats are not hunted at their daytime roosts but may be killed at a distance from the roost during the night. Numerous such examples can be found in all parts of the world.

Some traditional communities have developed detailed resource regulation systems. For example, many traditional communities – whether "indigenous" or "tribal" like the Tará'n Dayaks of West Kalimantan or the nontribal, such as the ribereños of Amazonian Peru – establish community reserves and formulate rules about how the species therein can be exploited, with the expressed intention of preserving these resources for the existing community and for future generations. Therefore, in some cases reserves may be protected by religious sanctions and in others by a more overtly "social" contract and enforced by strong economic and social sanctions; combinations of approaches are also found.

Biological diversity may well have been higher in rural areas in former times, when large numbers of farmers of many different cultures had long-term stakes in the land they farmed and had control over their own technology. These historical systems of land management were highly variable, following a range of different rules to take into account specific attributes of the physical systems within which they were found, cultural views of the world, and the economic and political relationships that existed in the setting. Despite their great diversity, such systems often had characteristics such as clearly defined boundaries, specific rules on the harvesting of different products, involvement of the affected people in these collective choices, a system of monitoring the use of resources, cultural sanctions for those who violated the operational rules, inexpensive local mechanisms for resolving conflict, and ways of organizing these activities so that different types of decisions were taken at different levels.

Urban Versus Rural Perceptions

About half the world's population today lives in urban settings far removed from the agricultural systems on which their lives depend. While rural peoples typically have a very good practical understanding of biodiversity, those living in cities increasingly have no more than a theoretical understanding, perhaps reinforced by an occasional visit to a national park or by a television program about nature. The growing numbers of nature-based films, protected areas, and forms of tourism based on idealized visions of nature indicate that urban people still feel a need to connect to biodiversity. Of course, different cultures have different perceptions, and the diversity of human societies is reflected in the diversity of perceptions urban people have of their environment. Any classification of such cultural values will necessarily mask some of this diversity, but rural people who live in close contact with the realities of nature typically have very different attitudes about biodiversity from urban people who have only a distant relationship with nature. Examples of these contrasting attitudes are presented in [Table 1](#).

Table 1 Rural and urban attitudes about biodiversity

<i>Rural attitudes</i>	<i>Urban attitudes</i>
Humans as one part of nature's biodiversity	Humans not part of biodiversity
All living creatures considered equal	Humans superior to all creation
Culture/nature as a continuum (no such thing as wilderness)	Culture/civilization human, and nature considered wild
Natural way is right, and human activities should be molded along nature's rhythms	Human technology is superior, needs to mold nature to suit human needs
Biodiversity has an integral set of multiple values (cultural, spiritual, material)	Biodiversity is predominantly a material (economic) resource

These attitudes are ideal types, and will not necessarily be found in their pure forms in any rural or urban community. Rather, societies both over time and over space can be placed on a continuum between these opposites, as human attitudes change due to both internal social dynamics and external influences. However, it is clear that such attitudes greatly influence how humans use natural resources and therefore the impacts they have on biodiversity.

In marked contrast to the rural areas where people still live in a close relationship with biodiversity, urban dwellers are able to gain the benefits from the biodiversity of the entire globe. Their connections through trade and communications enable urban dwellers to have rapid and unprecedented access to biodiversity. Ironically, the expanding access to more biodiversity has tended to weaken the feedback between human welfare and the way biological resources are managed; the urban dwellers typically have only the very faintest notion of how their consumption might have impacts on biodiversity in the countryside of a distant country.

Conclusions

Establishing a connection between specific cultural practices and conservation or enhancement of biological diversity is by no means a simple matter, for the overtly declared purpose of a practice that seems to help conserve biological diversity may in fact be quite different. Thus, in South Asia many sacred ponds have helped conserve the indigenous fish fauna. But people may leave these ponds alone out of respect for some deities, not with an expressly declared purpose of conserving fish diversity. It is then quite possible that many cultural or religious practices that seem to promote conservation may have originated from different motivations, while others declared as promoting conservation may in reality achieve something very different.

Traditional societies have often protected parts of the natural landscape they live in, or left untouched some of its elements. Most such societies, for instance, have considered certain sites as sacred, where most or all human activities are prohibited. Most societies have also considered certain species as sacred, with elaborate myths and folk tales about how humans originated from such species, or how these species are incarnations of gods and deities, or in some way associated with them, or how they

obtained magical powers. These could be wild species that are left undisturbed (and therefore have survived in even the most densely populated and radically altered human landscapes, such as rhesus and bonnet macaques in Indian cities) or domesticated plants and animals whose utilitarian value is intertwined with spiritual values (such as the cow in Hinduism). Such belief systems can have the effect (although perhaps unintentional) of regulating resource use.

A rich literature of traditional conservation practices indicates that they have been a common feature for many cultures over many years. This literature indicates that such practices serve group interests of communities and remain viable only so long as (1) local communities continue substantial levels of dependence on resources harvested from their immediate vicinity, (2) local communities have full control over the local resource base, and (3) local communities retain a sufficiently high level of internal cohesion. In most cases, these conditions are no longer fulfilled when outside state or corporate bodies establish control over natural resources.

When local people are part of a local ecosystem, their behavior directly affects their own survival. But cultural mechanisms that have been developed as adaptations to the environment over tens or hundreds of generations are quickly cast aside when trade or new technology frees people from traditional ecological constraints, changing them from "ecosystem people," who are adapted to their local ecosystem, into "biosphere people," who often live in cities and can draw from the resources of the entire world.

While changes in traditional attitudes toward biodiversity can be a result of internal dynamics (e.g., population increase), they are perhaps more often a result of outside influences: interaction with a modern culture, intrusion of the market, a technical innovation imported from another culture, and so on. Some have argued that traditional resource use patterns may be sustainable only under conditions of low population density, abundant land, simple technology, and limited involvement with a market economy. When confronted with market pressures, higher population densities, new technologies, and increased opportunities, few indigenous peoples appear able to maintain the integrity of their traditional methods, even when these are reinforced by religious beliefs.

Glossary

AZA Association of Zoos and Aquariums, a North American professional organization.

Ex situ Outside the natural range. Hence, a captive breeding program in Europe for a South American species would be an *ex situ* program. (Conversely, a Chinese program to breed native panda bears in captivity is an *in situ* breeding program because it is within the natural range.)

Exotic animals Animals that have not been domesticated for use by humans in agriculture or as pets; also connotes that the wild animals are from another region of the world.

Founders Animals that were collected from their natural range and that have produced progeny in captivity (and are assumed to be unrelated). Thus, these animals are the

founding stocks of the captive population. Also generalized to include animals with wild parents that are collected in order to supplement the genetic diversity of an established captive population.

International Species Information System (ISIS) A central repository for zoo animal records founded in 1973; has also developed the computer programs that most zoos use for keeping their animal records, as well as software used by zoos for studbooks.

Studbooks Also called genealogies, registries, or pedigrees, a database of historic and living animals intended to go beyond passively recording bloodlines and records; typically kept in computer databases that are also useful for actively managing the genetics, demography, and husbandry of captive populations.

Introduction

Zoo is a handy three-letter word, and thus in this article “zoos” will be used in a very general way to include any public or private institutions that house live exotic animals, largely for the purposes of exhibition to the public. Zoos are permanent establishments that are open to the public to provide education, recreation, and cultural enjoyment. Zoos, for purposes of this discussion, are not transient shows such as circuses or petting zoos. Nor are zoos private collections of exotic animals. “Zoos,” defined thus, include the facilities that are traditionally considered zoos, such as zoological parks and aquariums, and also many wildlife centers and “bioparks,” as well as some insect houses and *ex situ* breeding centers. There are currently over 1200 well-established zoos worldwide.

Zoos reach a vast audience; for example, North American accredited zoos attract more visitors, currently estimated at over 175 million annually, than the major professional sports combined. Worldwide, zoo attendance is estimated at over 600 million visitors (Gusset and Dick, 2011). The best modern zoo exhibits are sublime, invoking in visitors a sense of awe

and respect for nature. Zoos are increasingly operated by specialized, professional staff in partnership with government and private interests, with the express goal of conserving wildlife. The main focus of this article is on how zoos are evolving into institutions for wildlife conservation, and also on the art and science of managing biodiversity in zoos.

The Changing Role and Facade of Zoos

Zoos from Ancient to Recent Times

Zoos probably arose as places of spectacle and entertainment shortly after civilization became urbanized. The first recorded zoological collection dates to 2500 BC, when several thousand wild animals are documented in Saqqara, Egypt. Ancient Egyptians kept many wild species for use in religious ceremonies, or perhaps because they hoped to tame them. These ancient animal collections were acquired as tribute gifts or via expeditions that were mounted specifically to collect wildlife.

Zoo collections have sprung up independently on many continents and in many civilizations. For example, Chinese

emperors as far back as 1150 BC had walled animal collections they called “parks of knowledge.” When Cortés reached Mexico City in 1519, he witnessed, and then destroyed, the Aztec ruler Montezuma’s immense zoo and gardens. Montezuma’s zoo was so large that 300 keepers were employed for the aviaries alone, and it even housed malformed humans as part of the collection. Most of the zoological collections of antiquity were imperial and exclusive – symbols of wealth and power. They were menageries in the sense that they were collections of living trophies to be managed.

Collections during Roman times were also for the amusement of citizens. Large numbers of wild animals were used for blood sport and spectacles; holding areas that also allowed public viewing, called *viveria*, were associated with arenas. After the fall of Rome, collections of wildlife were not so common in Europe. During Europe’s Middle Ages, imperial menageries once again became more significant. Wild animals were used as diplomatic gestures – as tributes and ceremonial gifts.

The roots of public zoos are somewhat contemporaneous with the emergence of Europe’s great cities. London gained a zoo, of sorts, in 1252 when Henry III transferred his menagerie to the Tower of London; London’s citizens were pressed to support the menagerie, and in turn the public could view some of the animals, such as a polar bear and an elephant. Urban menageries, under the sponsorship of merchants and other citizens, began to emerge, first in Frankfurt in the late 1300s, then in the 1500s at The Hague and in Augsburg.

The rising profile of zoos can be traced to the Renaissance, when trade and exploration brought more animals into Europe. Colonial officers in far-flung empires served as conduits for animal requests. Public interest was most piqued by the wildlife of Africa and the Far East. The first zoological garden, which combined displays of plants and animals, was established in Versailles by Louis XIV in 1665; in 1794 this collection became a division of Paris’ natural history museum, creating a formal link to zoological research that was later emulated by many other zoos and museums. The first “modern” zoo that survives to this day is probably the Schönbrunn Zoo in Vienna, originally established as a private collection in the 1770s, but to which the public were intermittently admitted.

The nineteenth century has been hailed as the century of science and the golden age of museums. This century witnessed an explosive increase in the numbers of zoos and museums. Scientific societies sprang up, including zoological societies. Zoological research was nominally based in nineteenth-century zoos, but the inquiry was mostly limited to collecting and classifying. Local governments tended to operate zoos of this era with the aim of providing recreation and edification for the increasingly better-educated citizenry that arose with the Industrial Revolution. Zoos were sources of civic pride, and they competed to exhibit as many kinds of animals as possible. The rise of print media made it possible for civic leaders to compare collections more readily with rival zoos. Natural social groupings were largely ignored, and frequently solitary animals were displayed. Generally species were grouped to correspond with scientific classification, for instance, into bird, reptile, or carnivore houses. These animal collections were viewed as analogous to collections of art, and even the zoo architecture of the period came to be considered art.

An innovation at the beginning of the twentieth century was habitat exhibits, as pioneered by Carl Hagenbeck at Tierpark, outside Hamburg, Germany. In these zoos of living panoramas, it became increasingly common to display animals along geographic lines rather than strictly taxonomic ones. Habitat exhibits were well suited to zoo designs that intended to teach ecological principles, and thus led to the display of animals in more natural social groupings. Eventually mixed-species exhibits became more common, and these conglomerations might even be grouped by ecological biomes such as “polar zone” or “tropical zone,” rather than along strictly geographical or taxonomic lines.

Later in the twentieth century, world culture became increasingly electronic and graphic. Zoos found themselves in competition with wildlife film documentaries. No longer would the animal displayed in a sterile cage suffice for an increasingly sophisticated audience. “Immersion” exhibits became the ideal for most new zoo development. Immersion exhibits are ones that seek to make visitors feel that they are in the habitat with the animals. This may be accomplished by incorporating the same details of rocks, logs, or plants into both the animal and the public space, using these same details to hide any cage elements, and also by special effects such as mist machines and animal call background soundtracks that help create an illusion. Barriers to separate animals and people may be relatively invisible (e.g., glass) or carefully placed so they are unobtrusive. Special feeders and techniques of animal management may be used to encourage animals to be active and visible – for example, hidden heating or cooling pads for animals to lounge on, depending on season, or feeders that intermittently spray out small amounts of food near a viewing station to encourage visible foraging behavior. Zoos often try to craft the visitor space so that visitors do not see other visitors while observing the animals. In many instances, the designers’ intent is to evoke an almost religious experience of awe and respect for nature, much as the grand cathedrals did in early eras.

Rise of the Zoo Conservation Ethic

Zoos, as we have seen, arose as places of spectacle, not as conservation organizations. But many modern zoos have chosen wildlife conservation as their primary mission. The conservation ethic has developed in zoos over the past century in parallel with the nonzoo world, and in many cases one can point to zoos as the places that incubated the people and ideas that have led to important conservation developments (Norton *et al.*, 1995). The National Zoo in the United States, founded in 1887, is considered to be the first zoo created to preserve endangered species.

Conservation of wildlife and wildlife habitat has become the major goal of most of the prominent zoos and zoo professional organizations (IUDZG/CBSG (IUCN/SSC), 1993). Although altruism is part of the reason for the shift, compelling utilitarian reasons also drive these lofty goals. As humanity expands and wild places contract, exotic animals are getting scarcer, thereby reinforcing the zoo conservation mission while presenting the reality that zoos must become net producers of wildlife if their animal exhibits are to remain vibrant, inspirational, and of a multifaceted significance to

conservation. As regulators seek to simultaneously protect their natural resources and their agricultural sectors, governments make it ever more difficult to import and export wildlife. Wild animals may carry diseases that will harm livestock and perhaps even spread to the human populace; increasing understanding of disease has led to import restrictions or quarantines. For example, the bird-importing era, at least in the United States, slowed markedly in the early 1970s, when quarantine laws were enacted to guard against Newcastle's disease. In the 1990s the Wild Bird Trade Act was passed in the United States to restrict importation of any birds protected by CITES, the Convention on International Trade in Endangered Species of Wild Fauna and Flora. Most professional animal dealers have gone out of business due to the increasing restrictions, and zoos collectively have supported these regulations as part of their conservation mission.

Simultaneously, zoos have needed to import fewer animals because they became more proficient at keeping and breeding wildlife. Zoo keeping is a complicated art and science, and zoo keepers and managers have found it useful to pool their knowledge. Furthermore, single zoos are rather like islands from a population biology point of view, in that they are not big enough to sustain viable populations. So cooperative breeding programs for animals have become key, while cheap, fast transport, usually by air, makes it feasible for distant zoos to exchange breeding stocks. In many regions of the world, the leading zoos and their staff now belong to professional organizations. There are also world zoo organizations that help link the regions. These organizations have codes of ethics and accreditation (certification) programs. For example, North America's American Zoo and Aquarium Association (now renamed the Association of Zoos and Aquariums or AZA) was founded in 1924 and currently includes 223 accredited institutional members (this is about one-tenth of the number of animal exhibitors that are licensed with the US government).

Public support is yet another motive for many zoos to become conservation organizations. Zoos experience challenges in the competition for public funding. Modern zoos are costly, with expensive professional staffs, sophisticated veterinary medicine facilities, and a public that demands complex, educational, and artistic exhibits (Conway, 1986). Municipal governments are increasingly burdened by social programs and other competing demands for funds and now only fund a fraction of zoo operations compared to earlier times (on average 21% of the zoo budget in North America). But while the funding situation is tough in the richer nations, it is often quite desperate in poorer regions of the world. Most zoo-based conservation is being done by the "haves" whereas much of the need for conservation and access to endangered species is in the "have-not," largely tropically located zoos of the world.

There is enormous public support for environmental causes and grants available for conservation programs. Despite a vocal minority of critics who question the ethics of keeping animals in zoos, zoos are maintaining enormous popularity as they further refine their role as advocates of, and players in, wildlife conservation (Falk *et al.*, 2007). Zoos have often contributed significantly to the economies of their regions. AZA figures indicate \$15 billion in annual economic activity

among the AZA-accredited zoos and the support of 142,000 jobs. For instance, the Chicago Zoological Society estimates that their Brookfield Zoo generates \$150 million to the Chicago area whereas the four zoos and aquariums run by the Wildlife Conservation Society in New York City are worth approximately \$350 million to New York.

Animal Welfare in Zoos

Advocates for animals are becoming increasingly strident, even to the extent of using terrorist tactics. Their ire is more typically directed against laboratories that use animals, but zoos also have come under fire. Some animal rights extremists have expressed a goal of putting zoos out of existence. Extreme though these views may be, they signal a shift in public attitudes toward animal welfare. Many people now consider animals as fellow creatures with needs and feelings that should be respected. Zoos that have not become attuned to perceptions of animal welfare have often experienced an erosion of public support, often regained by a renaissance of rebuilding on existing or new sites and hiring some of the best professionals in the business. Some of the poorer, old-fashioned zoos have closed.

These animal advocates often confuse animal rights with animal welfare, and their anthropomorphic ideas about what animals need are often at odds with what is best for animals. For example, well-meaning protestors tried to prevent the transfer of a gorilla named Timmy, who had never procreated, to a zoo in New York that had considerable success in breeding gorillas as well as many potential fertile mates for Timmy. The protestors did not want Timmy to be separated from his current, infertile female partner. However, in nature gorillas do not form monogamous bonds and they do transfer from one social group to another. Eventually, after a court found the transferring and recipient zoos to be in total compliance with both the Endangered Species Act and the Animal Welfare Act, Timmy was moved, formed bonds with new females, and has begotten numerous offspring.

A related problem that we shall return to in the section Keeping Biodiversity is the problem of limited space in zoos. Thus, breeding unwanted, "surplus" animals is a problem for zoos because surplus animals inhabit valuable space. Some zoos take the apparently logical stance, from a utilitarian animal management vantage, of culling their surplus stocks or selling them to the private collectors. In private hands, some animals have ended up on game ranches where they are shot for sport. This has caused major public relations imbroglios, as a result of which zoos have had to examine their ethical policies and restrict their animal trade to accredited zoos. Zoos have developed contraceptive and husbandry techniques to prevent unplanned breeding, and they have developed scientific breeding plans to keep population demographics aligned with available space. Furthermore, there has been a trend of exchanging animals without fees as they become increasingly priceless.

Improved contraception for animals is just one example of how health care for exotic animals is becoming increasingly sophisticated. Improved veterinary care deserves much of the credit for allowing zoos to shift from relatively sterile concrete and steel cages to more natural housing, which is often,

literally, dirty (as the substrate is frequently dirt or other organic matter). Most zoos now have their own veterinarians and veterinary hospitals. Some even have pathologists, endocrinologists, and nutritionists providing preventive care, better drugs, and diagnostics. The understanding of wild animals' nutritional needs is advancing rapidly, and there are now numerous commercial brands of food for exotic animals, such as "Flamingo Fare." Nutritionists are even improving on fish diets (which are expensive and become depleted of certain vitamins during shipping and storage) for animals such as penguins and sea lions by devising a gelled, artificial fish in a fish shape. Most zoos have "browse" programs to grow and harvest fresh plant foods for their denizens.

There are numerous technical periodicals, books, and other publications related to zoo husbandry, including *Zoo Biology*, the zoo profession's peer-reviewed science journal, *International Zoo News*, the *International Zoo Yearbook*, *The Shape of Enrichment*, and *The Dodo*. As a testament to the improving welfare of zoo animals, zoos are now recording many longevity records, and zoo animals frequently senesce and die of old age – an almost unheard of occurrence in nature. As zoos have become more successful at keeping exotic animals alive and meeting their physical needs, the attention of zoo biologists has begun to shift toward behavior.

Zoos have also added applied psychology to their toolkits. They now must reassure their public that animals are not distressed but are potentially "happy." New techniques are being developed to stimulate zoo animals, reduce psychological stress, and elicit cooperation rather than coerce desired behaviors (Shepperdson *et al.*, 1998; Watters and Wielebnowski, 2009). Some zoos train animals to perform in shows, which is not a new phenomenon. But modern shows demonstrate natural behaviors to the public and keep the performing animals occupied, rather than emphasizing cute tricks or an animal's fierce nature. These new techniques range from behavior management and operant conditioning to environmental enrichment. Behavioral techniques aim to banish boredom, eliminate stereotypic tics, and otherwise encourage behavioral patterns that approximate those of animals in nature. For example, the Chicago Zoological Society has made a major commitment to behavioral science as it applies to zoo animal management through their Center for the Science of Animal Welfare (see <http://www.brookfieldzoo.org/czs/Animal-Care/Center-for-Science-and-Animal-Welfare>).

Emerging Trends

Zoos, as we have seen, have evolved from imperial menageries to the modern habitat and immersion exhibits that feature animals in more natural settings and social groupings. In the twenty-first century, we expect this trend toward more ecological themes to continue, with more zoos featuring animals in diverse, mixed-species exhibits. Zoos that predominantly have these diversity-designed exhibits have been given the moniker "biopark," or "biodome." This sort of zoo may feature botanical collections housed with terrestrial and aquatic vertebrates and invertebrates. There is a considerable art in developing these mixed-species exhibits, because zoos must ensure that cohoused animals do not decimate the foliage or

each other. Animals that do wreak havoc with plants or other animals are either excluded from the biopark or managed separately, although their exhibit boundaries may be crafted carefully so that this is not obvious. Some zoos are extending this idea to focus on the ecology of a certain region using both zoo exhibits and more museum-like exhibits; typically the focus may be the region in which they are located – for example, the "living desert museums" in the American southwest near Tucson, Arizona and Palm Springs, California.

Also emerging in the twenty-first century seems to be a new trend, which we shall call "conservation edu-tainment." These thematic exhibits have a storyline to which visitors may be introduced, sometimes through videos or costumed actors, as they wait to enter the exhibit. This visit may even include an amusement-style ride; for example, Sea World visitors to the polar region exhibit experienced a "tundra buggy" simulated ride before viewing polar bears and other creatures. Some call this the "Disneyfication" of zoos, after a zoo, "Disney's Animal Kingdom," that the Walt Disney Company opened in Florida in the late 1990s; one feature is a drive-through, safari-style bus ride, where the storyline is that visitors are joining a patrol to catch poachers.

The actual educational value of these new-style zoo exhibits is debatable, and a still greater unknown is whether the lessons learned by visitors will translate into conservation actions. Conservation education, zoos have argued, is one of their major contributions, one that is becoming increasingly important as citizens become further distanced from nature. Zoos are trying to justify these claims, and also to do a better job of conservation education. Thus, zoos are beginning to scrutinize their exhibits and programs using evaluation techniques. Evaluation methods, including surveys, interviews, or observation of visitors, are sometimes employed during the design phase to improve the message before expensive construction begins. They may also be used at other times to help fine-tune exhibits or otherwise inform about how the zoo is working or what the audience is like. The science of evaluation is rapidly developing in zoos and museums, and it will probably become an increasingly important part of zoo planning for quantifiable conservation outcomes and mission accomplishment (Falk *et al.*, 2007).

As the world becomes more wired to the Internet, zoos are following suit. Many zoos now have websites where visitors can find information about the zoo, and many also use social networking media. Some zoo databases, including the vast International Species Information Service (ISIS) registry of zoo animals, are now available at Internet websites. The newly launched Zoo Information Management System (ZIMS), aims to increase information sharing about collections for better animal management and population sustainability. Some zoos are incorporating electronic media into their educational efforts, either integrated with exhibit graphics or separately. Cooperative breeding plans, and the data needed to manage them, will increasingly be shared via electronic means. And some website programs (for example, one for trumpeter swans) allow school children and others to dynamically follow the movements of reintroduced animals via satellite tracking. Virtual zoos will not keep real animals, which is the primary business of zoos, so zoos will probably continue to find ways to use the Internet that enhance rather than radically change what they do.

As the supply of wild-born founders dwindles, and more amenities are expected for the animals in hand, zoos are abandoning the one-of-each-kind collecting approach. Within-zoo species diversity is decreasing in order to make room for zoos to manage larger, more natural social groups and to house a breeding nucleus of at least several pairs and their young offspring of nonsocial species (Gibbons *et al.*, 1995). Many zoos are trying to allocate a proportion of their animal space for off-exhibit breeding efforts, and some are operating special facilities devoted to breeding of endangered species – mostly *ex situ* but also some *in situ*. Many zoos are developing specializations, concentrating their efforts on the specific groups of animals that they can keep best and exhibit most dramatically. Zoo workers are also becoming more specialized, both along taxonomic lines and also professionally into fields such as educators, veterinarians, nutritionists, population biologists, behaviorists, life-support system operators, pathologists, and horticulturists. With the increasing need for cooperation, more formal committees and other structures are developing through the professional organizations.

Choosing Animals to Promote Biodiversity Conservation

Space, the Final Limit

Modern zoos are expensive to build and upgrade. In North America alone, zoos spend millions of dollars per year on capital or physical improvements, with much larger expenditures for major new exhibits or zoo facilities. A major exhibit can cost in the tens of millions of dollars and typically takes at least 3 years to plan and build. Maintaining a zoo and its animals is also very expensive. Therefore, there are practical limits to how many zoos can be supported and thus to how many animals can be maintained by zoos (Conway, 1986). For example, the number of animals that are presently kept in the 223 accredited zoos of North America is approximately 870,000 from among 6000 species.

Thus, conservation-oriented zoos choose their inhabitants with care in order to maximize the biodiversity that they preserve in their finite space. A biodiversity trade-off must be made between the number of species that are maintained by zoos versus the genetic diversity or size of the captive populations that are maintained. Zoo planners have to think long-term because they are trying to maintain viable populations for decades or centuries. In many cases, zoo populations are, essentially, closed gene pools because it is difficult or impossible to acquire new lineages or wild-caught “founders.” Extinction in nature is the most obvious cause for a closed captive population, and zoos work with several “extinct” species such as the Prezwalski’s horse. But species that are extant in nature can also be effectively isolated in zoos by government import or export regulations, concerns about disease transmission, rarity in nature, political issues, or the extreme difficulty and expense of collecting some species. In most cases zoo planners also try to “save all the pieces” by managing their populations for genetic variability. Genetic variability is an achievable objective since anything approaching natural selection is by definition impossible while

the animals are under human care. Arguably, this is a prudent and responsible strategy should the animals be needed someday for restocking wild habitats. Habitats are also changing, so the theoretically successful genetic profile of the past might not be the same in the future. By breeding for variability, i.e., retaining as much of variability as was present in the original wild-caught founders as possible, the potential for readaptation to old or new habitats is maximized.

Hence, zoo population plans usually strive to breed animals better than would be done randomly without a scientific framework, and they often try to do this by maintaining small, well-managed populations that are projected to be genetically and demographically viable well into the future. This usually requires a captive population of several hundred animals. In this effort, attention must often be paid to picking the right unit for conservation, or the evolutionarily significant unit. Zoos have funded a considerable amount of applied molecular genetic research in order to determine subspecies and species characteristics, thereby avoiding the possibility of breeding animals that are similar-looking but are in fact different species. The converse is just as problematic when members of the same species are perceived as distinct and maintained separately, taking up valuable space and/or compromising the viability of both populations with suboptimal numbers.

Metamanagement of Zoo Biodiversity

Each zoo is an island too small to do much conservation breeding on its own. To facilitate cooperation, organized conservation programs involving captive animals are beginning to develop around the world through regional zoo professional associations. Most of the labor that goes into these programs is pro bono or volunteer. Much of the work is accomplished through workshop meetings and via committee, at considerable personal and institutional expense.

The basic unit of these programs is the studbook, which is the database of historic and living animals in a particular captive population. Studbooks are usually maintained through the efforts of one “studbook keeper.” Populations that are monitored with studbooks can be managed through regional or even global captive breeding plans, usually overseen by a committee, which specifies where each animal should be and whether it should be bred.

To prioritize how much captive space various populations should be allocated, zoo specialist groups for each kind of animal have formed, and are known as “taxon (for taxonomic) advisory groups.” Taxon advisory groups typically work closely with the appropriate taxonomic and scientific specialist groups of the World Conservation Union (IUCN), as well as with scientific advisors. Regional taxon advisory groups tend to develop priorities that are complementary to those in other areas; for example, Europe may choose to allocate space to breed a different species of penguin than North America. Taxon advisory group priorities are formalized into “regional collection plans,” which ideally include a justification for including or excluding each species or subspecies in the taxonomic group, as well as setting a target population size for each managed population. These plans may also specify areas where research is needed, or where field conservation should

be a priority. Tools are being developed to facilitate regional planning, including metacollection software that has been developed by Australian zoos.

The representation of biodiversity in zoos is biased toward animals that are furry, large, brightly colored, or otherwise captivating for people. In general, the more closely related to humans, the greater the representation. So most kinds of primates are kept in zoos and managed through cooperative programs, whereas only a fraction of rodents or bats are represented. Similarly, most kinds of flamingos can be found in captivity, whereas only a fraction of the small perching birds are kept. A smaller proportion of birds are maintained in organized programs than mammals, but only a fraction of the scaly creatures (fish, reptile, and amphibian) are kept. Very few invertebrates are represented in captivity, but this seems to be changing as butterfly exhibits and insect displays are gaining in popularity. Invertebrate husbandry is relatively primitive for both aquatic and terrestrial species; the public generally considers the collection of wild invertebrates acceptable, so there has been less pressure to develop husbandry techniques. The situation for fish, and most other nonmammalian aquarium denizens, is similar to that of invertebrates.

Institutional Planning

Zoos as individual institutions are also becoming very mission-oriented. Many zoos have developed mission statements and master plans for growth and development. These plans provide the overall organization of the zoo exhibits and the visitor traffic patterns as well as locations of facilities for merchandise, refreshments, and bathrooms. (Bathroom location is amazingly important for a positive visitor experience!) Master plans usually designate the kind of educational messages the zoo will try to convey and the themes of the exhibits. They may be informed by practical considerations of what animals and plants will do best in the zoo, and these may be based on local climate or the experience and expertise of the zoo's staff.

Within the context of the master plan, zoo planners, typically curators, will develop an animal collection plan. Ideally, curators will develop these plans after studying the regional collection plans that have been developed for metamanagement of zoo collections. This collection plan will usually list each species that the zoo keeps or wishes to obtain, along with a justification for what the species will contribute to the zoo and to conservation of the species. The plan should say how many individuals there are of each sex, and how many are desired. The plan will specify where these animals will be housed. If the species is managed by a cooperative breeding plan, then the institutional collection plan should include the recommendations for which animals are to be bred and which are not. If not part of a cooperative plan, the curators should have a breeding and possibly a research plan of their own. Institutional collection plans usually need to be updated annually.

Keeping Biodiversity

Zoo Animal Records Keeping

Basic to managing animals and improving husbandry is keeping track of the inventory and gathering data. The

memory of zoo staff is no longer sufficient to keep these records, as animals live longer and breed better, the government expects more information, and both animals and keepers are more mobile. Zoos are tracking an ever-increasing amount of information about their animals. Each animal in the inventory, current and historic, is accessioned, which means it is assigned a unique identification number. The animal also must be physically identifiable, so most are tagged or marked; this can be done with traditional bands and tags or with more high-tech injectable microchips. Records are kept for diverse variables, including characteristics that allow an animal to be individually identified, dates of birth and death and other life-stage transitions, sex, parents, offspring, current and previous locations, health notes, cage mates, previous owners, physical parameters such as measurements, species and subspecies, and behavioral observations. Zoos are standardizing their data collection and records so that all this information can be pooled.

Keeping these records has turned into a specialty of its own, and the keepers of the data are usually called "registrars." Registrars may also be responsible for some of the government permits and paperwork associated with modern zoo keeping. These data are generally organized into a computer database. The most widely used program is Animal Records Keeping System (ARKS) that was developed by ISIS in 1985. ARKS generates a variety of standard reports. In addition, ARKS is useful for looking up simple questions about individual animals (for example, potential exposure to disease) as well as for mining the data to seek trends or clues to larger questions.

Most zoos send their ARKS data to ISIS at regular intervals so that it is backed up and also so that parts of the central database can be combined to create an international inventory. This international data is useful for various other purposes such as cooperative breeding programs, scientific research, or for governmental authorities. A weakness of ARKS is its limited ability to manage data for group-living or colonial species. Thus ARKS is of little use for managing animals such as schooling fish, many invertebrates, colony-nesting birds, or other animals that are kept in groups with multiple adult males and females. Similarly, animals that breed in relatively large enclosures (such as ducks in large ponds or fish in large tanks) are difficult to keep track of with individual records. Because of this weakness, animal records for aquaria and invertebrate collections are not standardized. As genetic identification becomes less expensive and more available, the possibility for tracking the genetics and demographics of large colony collections becomes much more feasible.

Zoo Population Management Strategies

Zoos have historically made much of their "babies," as births were and still are exciting events of much interest to the public. Prior to the development of management plans, rare breeding successes for a particular species tended to be replicated and replicated again. Then zoo curators would notice that there was a surplus of the species and they could no longer find good homes for the babies. Thus, all zoos would stop breeding the now-abundant species all at the same time. Some years later, as the stocks of the animal were aging and

starting to die off, there would again be room and demand for babies, and curators would try to resume breeding. But all too often, it would be too late for the aging stocks and the captive population would be lost.

To prevent these boom-and-bust breeding cycles, beginning with the launch of the Species Survival Plan (SSP) concept in 1980, zoo biologists have developed population management strategies and tools (Gibbons *et al.*, 1995). Key to zoo population management is gathering information about all the animals in the managed, captive population (the managed population often is not identical to the captive population because nonaccredited zoos and private collections are often not part of the cooperative program). The population data are kept in studbooks, which contain genealogical information as well as demographic information. As in zoo records keeping, ISIS distributes the most popular database for studbooks, a program called SPARKS, which stands for Single Population Analysis and Records Keeping System. The studbook programs integrate with computer software such as PM 2000, lately updated as PMx (PM=Population Management), that performs much of the demographic and genetic analyses that are essential to zoo population management.

Two principal kinds of conservation breeding programs are the current standards. The first is a program that participants essentially sign a contract to join, and agree to abide by the decisions of an elected committee. This type of program was first introduced in the United States, and was named the SSP; nearly identical programs are known by other names in other regions of the world. The second kind of program is a less intensive one, in which recommendations are issued but individual zoos elect whether or not to cooperate. In North America this second kind of program is known as a Population Management Plan (PMP). These two kinds of programs follow similar population management strategies but differ more in the intensity and politics of the actual management. The SSP also has conservation, research, and education components, whereas the PMP is strictly for population management. Recently, it became mandatory for AZA-accredited zoos holding SSP species to participate fully in the SSP-managed programs.

Planning for conservation breeding programs generally begins by determining the purpose of the program. Will animals from the population eventually be returned to the wild, or will the primary purpose of the population be for exhibition in zoos? The managers should decide what the appropriate population is for management purposes – for example, whether to limit the management to a subset of the animals that are known to derive from founders of the same subspecies, while excluding those that are of more uncertain ancestry. Once these decisions are made, demographic and genetic goals are set. Genetic and demographic analyses are done using the studbook data and specially designed software. The analyses are used to estimate parameters, which are needed for the long-range population forecasts that are used to guide the goals. Goal setting is done with the help of analytical tools that consider the number of founders (amount of genetic diversity that was likely to be captured), the effective population size N_e , the current population size, the rate of population growth, the number of years since the program was founded, and the generation time. Typically,

conservation breeding programs aim to preserve greater than 90% of the original diversity for at least 100 years. Sometimes it becomes apparent that demographic intervention is needed, perhaps to increase the population growth rate, lengthen the generation time, or increase the number of spaces available so that the population can grow. At other times managers realize that more founders must be imported, if possible from zoos in another region of the world, but sometimes from nature.

As an aside, zoos have sustained much criticism from conservationists for taking animals from the wild for exhibition, including charges that this has led to the depletion of wild stocks. Zoos rebut that the number of animals they take are trivial compared with animals that die through habitat loss, hunting, or other human activities. Good captive management reduces the number of founders, or wild-born breeding stock, needed for long-term population viability. Theoretically, the acceptable number of founders is 12–25 individuals picked at random from a wild population (25 being ideal since each additional founder beyond 25 is unlikely to possess genes not already present in the 25). However, many captive populations start with only a fraction of this number. Even with good management, new founders may need to be added, since not all founders will produce the ideal number of offspring. Founders should be collected with minimal impact on the wild population. The way that this is best accomplished depends on the natural history of the species and the specifics of the program. For example, one low-impact approach to collecting founders is to salvage orphaned or injured nonreleasable wild animals; this opportunistic approach has the disadvantage that it may be slow and that disabled wildlife can constitute poor breeding stock. In extreme cases, such as those of the California condor and black-footed ferret, all of the remaining wild individuals were brought into captivity at the point it was calculated that the wild population was on a trajectory to zero. In both cases, this proved to be the salvation of the entire species. Descendants of these last remaining wild specimens became the ancestors of captive-born animals used to reestablish several new wild populations in the species' historic range.

Once the goals of the population are determined, and plans are made to redress problems such as too few founders, a detailed conservation breeding plan is developed. These plans give a recommendation for each animal in the managed population, which will include whether the animal should be moved, if it should be bred, which animal it should be paired with, and whether any special actions are needed, such as fertility testing.

Scientific principles are given a heavy weight in the planning. Zoo biologists tend to start with demography, using a Leslie matrix approach that incorporates both current and historic data. The demographic software tools were developed at the National Zoological Park by Jon Ballou and Laurie Bingaman-Lackey. Demographic data sets for zoos are often small, but contain highly detailed information compared to wild populations. Therefore zoo demographic estimates are often very crude and may require considerable tweaking. Early in the analysis, zoo biologists look at the population's age structure and sex ratio. If these are skewed, efforts may be needed to create a better demographic balance. The next

consideration is rates of fertility and infant and adult mortality; these estimates are used to project the number of breeding pairs that will be required in order to end up with the desired number of births that will balance deaths and also generate the recommended population growth or shrinkage.

"Genetic representation" of individual animals is the primary variable considered in deciding the animal-by-animal breeding priorities, except that aging, genetically underrepresented animals with only a few breeding years left may be given special breeding priority. Genetic algorithms, largely developed by the Chicago Zoological Society's Robert Lacy, use pedigree-based genetic simulations to assess the genetics of each animal and potential pairing in the population. Managers attempt to simultaneously maximize three parameters when recommending breeding matches: (1) good matches will improve the genetic diversity of the population (i.e., by increasing underrepresented lineages), (2) good matches will attempt to balance the genetic value of male and female, and (3) good matches will avoid inbreeding with close relatives. Balancing the genetic value, which is done by looking at a parameter called mean kinship, or the effective number of close kin, is important because it breeds big families with other big ones and little families with other little ones. New ways of visualizing mean kinship are now being used in PMx so that mismatching of animals with different mean kinship values becomes less important. This is especially useful in managing polygynous species where other difficulties can emerge if genetic management trumps social management.

Although the science of conservation breeding has advanced considerably, practical considerations also must enter into planning. Wild animal keeping in practice is a complex art, and it would be foolish to ignore details such as the distance of a proposed transfer and behavioral and physiological observations. For example, there is no point in recommending a pairing of two gorillas that are incompatible. Similarly, if an animal has not bred after many attempts at several zoos, there may be a physiological problem, or perhaps managers have not yet tried the right trick.

Group-breeding species are a special challenge to zoo population biologists, as they are for zoo animal records keepers. The methods outlined above work less optimally for populations in which a significant proportion of the pedigree is unknown, and also when managers cannot control which individuals mate with which, as is generally the case with group-breeding animals. An approach that is sometimes used is to completely ignore the pedigree and manage the species as a subdivided population, with occasional transfers of animals between demes or subpopulations. But the pedigree-free approach often throws out large amounts of information about a population and results in overly conservative management that will require larger populations than might otherwise be needed. Similarly, species whose life history is more size-dependent than age-dependent are not well served by current methods, and may be better managed using stage-based population management. As zoos move beyond management of animals with relatively simple breeding biology, such as tigers, and tackle species with more complex life histories, new population approaches will be needed. Similarly, as the "brave new world" of reproductive technology develops, frozen zoos will need to become integrated into population planning.

Frozen Zoos and Other High-Tech Solutions

An alluring prospect is that someday we may be able to preserve biodiversity in bottles on a warehouse shelf. Another enticing prospect is the use of reproductive technology to propagate animals that have not reproduced naturally. New technologies are making these prospects possible in some cases.

"Assisted reproduction" is a catchall phrase for a variety of veterinary or endocrine interventions used to promote breeding (Gibbons *et al.*, 1995). Artificial insemination, using fresh or frozen sperm, has been in use for many years in the domestic livestock industry and also for some zoo animals. The techniques can be readily adapted to zoo animals if there is a closely related domestic model in which the technique has been developed; for example, rare species of cows can benefit from research with domestic cows. Zoos have also employed other techniques, such as *in vitro* fertilization with harvested eggs, or embryo transfer both within and between species. The idea of growing a rare species in the womb of a common one is appealing, and has been achieved in some instances.

"Frozen zoos" are being developed by several zoos. In these superchilled repositories, sperm, eggs, and embryos are committed to long-term storage. Now that cloning is also a real possibility, frozen zoos of living cell lines are also being developed (Ryder and Bernirschke, 1997). Saving biodiversity in freezers is tantalizing, but there are many limitations to this approach and hurdles to be overcome.

Assisted reproductive techniques are difficult and costly to adapt to animals that do not have a closely related model, and also for those with complex reproductive physiology, for example, animals with induced ovulation. By and large, the techniques for animals with shelled eggs have been limited to artificial insemination. We cannot, as of yet, grow embryos in a test tube, so those derived from a frozen zoo must be grown in a real womb (or egg). This means a real population of surrogates will be needed to mother the frozen zoo, although in some cases these surrogate mothers can be of a different species. Surrogate mothers may produce animals with species-inappropriate behaviors and possibly even a hybrid phenotype.

Frozen zoos will not preserve learned animal behaviors (culture), and they will not eliminate the need to keep real populations. Frozen zoos, cloning techniques, and the like, as San Diego's Oliver Ryder predicts, will probably become powerful adjuncts to the management of populations. So far, genetic and demographic models for managing zoo populations have not factored in frozen resources, but some day they probably will. This will allow managers to keep smaller numbers of living animals. In addition, relative to the transfer of whole animals, the transfer of sperm, eggs, and embryos between wild and captive populations can be done with far less risk of cotransferring disease-causing pathogens. Thus, these techniques may be highly useful in importing new gene lines into small populations, both wild and captive.

Supporting Diversity in Nature

The Ark Paradigm

Enamored, perhaps, with their newfound ability to breed and manage exotic animals, zoos and their commentators were for

a time fixated on the “ark” paradigm of conservation. That is, like the biblical Noah, they talked about saving species in captivity until sometime in the future when the flood of human population shall recede and there will again be the space, and also the will, to restore Nature. Zoos have actually had some success saving species this way. The list of species that have been rescued from extinction by taking refuge for some time in zoos is ever-growing and includes black-footed ferret, California condor, European bison, Mongolian wild horse, Arabian oryx, *Partula* snails, and Guam rails. However, some species have become extinct during their captive sojourn and no opportunity has arisen to restore some others – for example, several bird species of Hawaii. We are seeing that restoration of a fauna may be only a remote possibility and the utility of reintroduction overstated in some ways. Where species have been rescued by breeding and reintroduction techniques, it is nothing short of miraculous and remains a model worth pursuing and perfecting.

The Post-Ark Paradigm

Maintenance of captive stocks has several functions, but the singular purpose is not, as it is popularly misperceived, for future reintroduction efforts. Zoos may indeed rescue individual animals and sequester them in the safety of captivity. As zoo professionals look beyond the ark, they are developing many other ways to contribute to the conservation of exotic animals.

Exciting, educational exhibits are potentially zoos’ pre-eminent contribution to conserving animals and their habitats. Worldwide, zoos are estimated to attract over 600 million visitors annually. The majority of these visitors live in urban areas and otherwise have little contact with wildlife. Zoos are beginning to study and develop approaches for mobilizing visitors for conservation through innovative exhibit and educational programs. North America’s accredited zoos report that each year 12 million students visit and enjoy onsite education programs, and in addition 85,000 teachers profit from teacher training. Some zoos are even developing “museum schools” in which a zoo or museum actually serves as an alternative school for a small number of students who typically combine rigorous college preparatory curricula with hands-on or applied learning in the zoo setting (more information about museum schools can be found at <http://www.astc.org>). Zoo-based conservation education programs need not end at the exit gates. Zoo educators and graphic artists can also develop conservation curricula that can be used in other parts of the world, including the native range of some endangered species. There is a remarkable dearth of educational materials about most endangered species within their native ranges, and any effort that zoos can make to redress this problem will be most helpful. Zoos may also need to develop curricula that more directly address the biodiversity crisis, and they may need to reach out more effectively to decision makers (politicians) and leaders of commerce.

Zoos can serve as refuges for displaced, injured, or confiscated wildlife. Thus, zoos help wildlife authorities enforce regulations by providing homes for seized wildlife. In addition, many zoos maintain patches of artificial or natural habitats for native wildlife and can provide significant

breeding refuges for some birds and butterflies, and for fish and small animals that need relatively little space for a viable population. The Amphibian Ark, an international program (see <http://www.amphibianark.org/>), now addresses the amphibian crisis by engaging zoos in field research and conservation as well as inexpensive captive propagation programs.

Zoos sponsor significant basic research, often studies that would be difficult or impossible to accomplish with animals in the wild. Furthermore, zoos invest a considerable amount of money in research; for example, accredited zoos in North America spent \$51 million on scientific research in 1998. While developing technology and methodology for captive animals under relatively controlled conditions, zoos create expertise that is useful *in situ* – for example, guidelines for medication dosages.

Direct financial support of field conservation is another way that zoos are helping preserve biodiversity (Gusset and Dick, 2011). Since 2006, accredited North American zoos have been involved in more than 3700 conservation projects in 100 countries, spending approximately \$90,000,000. Another form of *in situ* conservation funding is for zoos in the wealthier nations to help improve the conservation impact of zoos in less-developed nations. Many zoos also sponsor member tours to see wildlife in nature, and they try to make arrangements that will have a positive impact on conservation.

The Ark Revisited

Human populations are still increasing and wildlife will continue to disappear. More direct conservation measures will be needed from all zoos. Zoos will be called on to provide refuge for more species as the wild populations dwindle. Shrinking wild populations in postage-stamp parks may need to be managed more like zoo populations, with infusions of unrelated lineages, potentially from zoo stocks. Intensive, joint, metapopulation management of *in situ* and *ex situ* wild animals will require both scientific and political innovation. Zoos may indeed help to save some wildlife from the flood of humanity, but they probably will not be acting as closed vessels. Rather, expect to see zoo-based conservation continue to become increasingly dynamic and interactive.

Glossary

Character displacement Pattern of geographic variation in which a character differs more between sympatric than between allopatric populations of two species.

Competition Interaction between individuals of the same or different species, whereby resources (e.g., food, space, mating partners) used by one are made unavailable to others.

Mutualism Symbiotic relation in which each of two species benefits from the interaction.

Resistance An individual's capacity to reduce the damage inflicted upon it by an enemy.

Specialization Evolutionary adaptation in a particular mode of life or habitat.

Tolerance An individual's capacity to sustain damage by an enemy with limited decrease in fitness.

Trade-off Negative correlation between traits, such that a benefit due to changes in the value of one trait is associated with a cost produced by changes in the value in another trait.

Virulence Degree to which a parasite reduces the probability of survival or the reproductive capacity of an individual host. A relatively avirulent (benign) parasite has little impact on its host's fitness.

Meaning and Varieties of Coevolution

(1) *Patterns of correlated evolution*, especially *phylogenetic congruence*, among species or other lineages are usually detected by phylogenetic analysis. In extreme cases, the phylogeny of one clade of species, such as host-specific parasites, is congruent with that of a clade with which it interacts such as host species (Figure 1(a)). Such congruence would require *coincident speciation* of hosts and associated parasites. Deviations from perfect congruence might be caused by speciation of a lineage but not its associate, by extinction of one but not the other, or by a parasite switching from one host to another (colonization) (Figure 1(b)).

In some cases, the coincident speciation that underlies concordant phylogenies may be caused by the interaction between associated species. However, concordance might stem solely from a shared history of geographic isolation, without the interaction having played any causal role. Although phylogenetic concordance does not in itself provide evidence of reciprocal adaptation of the interacting species, it does imply extended historical opportunity for adaptation to have occurred. The greatest phylogenetic concordance has been described for some maternally transmitted endosymbiotic bacteria and their eukaryote hosts, and for certain ectoparasites (e.g., lice of gophers) that are primarily transmitted by contact among conspecific hosts. In many groups of parasites and herbivorous insects, related species are associated with related hosts, that is, members of a clade, but the phylogenies of the two clades are not congruent. This pattern often implies a long history of association, but one that has included shifts of parasite lineages among host lineages.

(2) Coevolution consisting of *reciprocal adaptive responses* has been rather arbitrarily classified as *specific* (or pairwise, or tight) coevolution and *diffuse* (or guild) coevolution. Specific coevolution is reciprocal adaptation of two species, independent of their interactions with other species, whereas diffuse coevolution occurs

when evolutionary change in one species affects its interaction with two or more other species (e.g., a change in a host that affects two parasite species). Specific coevolution is easier to visualize, model, and detect. Diffuse coevolution is most likely to occur when a species' response to selection by one interacting species is accompanied by genetically correlated effects on its interactions with other species. The term "diffuse coevolution" has also been used to describe nonadditive selection on one species by two or more other species, owing to an interaction between them or between their effects on the recipient species.

(3) *Cospeciation* may be induced by the interaction between species, but this probably requires special conditions. A likely case is in figs (*Ficus*) and the highly host-specific seed-eating wasps that pollinate them. Divergence between population of either a fig species or a wasp species in features governing the host preference of the wasp may engender divergence in the figure resulting in reproductively isolated populations of both. Such cospeciation may result in concordant phylogenies.

(4) *Escape-and-radiate coevolution* describes a scenario in which an evolutionary lineage diversifies after it evolves a defense that breaks its association with enemies. Such a scenario was first proposed by P. R. Ehrlich and P. H. Raven for plants and herbivorous insects. In this hypothesis, a plant lineage that evolves a novel defense sheds most of its herbivores, and therefore (by an unspecified causal inference) diversifies into many species. Only later do some herbivore species adapt to one or more of the plant species, and diversify in turn.

Collectively, these hypothetical scenarios suggest that coevolution may increase both the numbers of species and the phenotypic diversity (disparity) of species by selecting for the many characteristics that affect their interactions. Coevolution may therefore be an important engine of biological diversity, but we shall shortly note that coevolution may also cause extinction.

Often, the adaptation of one species to others is obvious, but reciprocal adaptation of the others is not. Because we seldom know a priori whether or not adaptation has been

Figure 1 Congruent (a) and incongruent (b) phylogenies of hosts (solid lines) and parasites (dashed lines). Letters indicate most closely related taxa. Each parasite taxa is specialized on the host with which it is closely associated in the diagram.

reciprocal, adaptations to ecological interactions are often loosely referred to as “coevolutionary,” even if evidence for reciprocity is slight or lacking. Certainly the study of coevolution includes adaptations to other species, which may or may not prove to have adapted in turn.

Evidence of Coevolution

Sources of Evidence for Coevolution

The study of coevolution comprises the same approaches as studying evolution in general. As in the broader field, the first

forms of evidence for coevolution consisted of detailed natural history observations, descriptions of the diversity of adaptive structures that mediate ecological interactions, and comparison among populations and species.

Charles Darwin published the first comprehensive illustration of how intricately species are adapted to one another and how structural complexity can be explained by coevolution in his description *The Various Contrivances By Which Orchids Are Fertilized By Insects* (1877). By comparing the shape of different orchid flowers and their associated pollinators, Darwin demonstrated that certain moth features are needed to successfully obtain nectar from the flower, features that are indeed exhibited by their specialized pollinators. By restricting nectar collection to a few pollinators, orchids increase the likelihood of cross-fertilization. Such is the correspondence between flower and pollinator shape that on observing the 29-cm-long nectar-bearing spur of the Madagascan orchid *Angraecum sesquipedale*, Darwin predicted the existence of a pollinating moth with a proboscis of that length. Such a moth, *Xanthopan morgani praedicta*, was indeed discovered 40 years later.

The description of patterns in plant use by lepidopteran larvae preceded the concept of *escape-and-radiate coevolution*. Higher taxa of butterflies often feed upon a single group of flowering plants. While some feed on more than one plant family, these tend to be closely related or have similar biochemistries. For instance, larvae of the butterfly subfamily Pierinae, or whites, feed predominantly on the families Capraeaceae and Brassicaceae, which are closely related. Some whites also feed on members of the family Tropaeolaceae that share with the other families the production of mustard oil glycosides and a rare fatty acid. These regularities imply an important role for plant secondary metabolites in determining butterfly host use. Given that these compounds affect herbivore behavior, acting often as deterrents, secondary chemistry may have constituted the key feature that allowed plant escape.

Comparisons among conspecific populations have also been suggestive of coevolution. The coloration pattern of the butterfly *Heliconius erato*, thought to be a signal to predators indicating distastefulness, varies among populations in Central and South America. Strikingly, the wing coloration of *H. melomene*, an equally distasteful congener with distinct life history and host preference, varies geographically in parallel with *H. erato*. This pattern is thought to be an example of coevolution of mimicry between prey species that share a predator. Fritz Müller, a contemporary of Darwin, first suggested this particular model of coevolution to explain similarities in wing pattern among unpalatable butterfly species belonging to two distinct genera (*Ituna* and *Thyridia*).

Müller also introduced the use of mathematical models to study the coevolutionary process. Modern mathematical and computer simulation models may incorporate population genetics, quantitative genetics, evolutionary game theory, and optimality theory. Mathematical modeling has proven useful in describing the dynamic of the interactions between species and in determining which conditions favor coevolution.

Although ecological interactions usually do not “fossilize,” the analysis of paleontological records has provided some evidence of coevolution. For instance, the appearance in the

Ordovician of predaceous cephalopods is associated with the simultaneous appearance of several defensive strategies on the part of their prey (e.g., strong sculpture and coiling in gastropods and shell-bearing cephalopods, spines in echinoderms), suggestive of diffuse coevolution between predators and their prey. The antiquity of certain interactions may also be determined by inspecting fossils of extant species. Several plant families possess structures (domatia) that harbor mites, which attack plant enemies. Domatia similar to the modern form have been discovered in fossilized leaves from the Eocene, 55 million years ago!

The relative age of clades of associated taxa is relevant for demonstrating correlated coevolution or co-speciation. These processes would be necessarily excluded if one group were much older than the other. The age of an association, or of interaction-related adaptations, can often be estimated from phylogenies with time calibration (e.g., using approximate molecular clocks or stem-group fossils). Molecular evidence from deep-sea vesicomyid clams and the sulfur-oxidizing endosymbiotic bacteria on which they depend for nourishment indicates that the interacting clades are both approximately 100 million years old. These two lineages appear to have been in close association since their origin and to have cospeciated, as indicated by the remarkable level of congruence between their estimated phylogenies. Phylogenetic information also becomes relevant in testing whether a character is an adaptation for an ecological interaction or an ancestral feature that exists in the absence of the interaction.

In some instances it has been possible to document the particular genes that affect a species' interaction. H.H. Flor found several genes in flax (*Linum usitatissimum*) that provide resistance to the rust *Melampsora lini*. Rust virulence is determined by a set of complementary genes, in a one-to-one relationship. This study inspired the gene-for-gene model (see Special Features in Parasite-Host Coevolution: Gene-for-Gene Systems), which has become a paradigm of phytopathology. Most traits, however, have a complex genetic basis, involving many genes. Such complexity requires a quantitative genetic approach, which partitions the trait variation into genetic and environmental components. This approach has demonstrated that many of the traits relevant to interactions have genetic variability, that is, there is potential for coevolution. For example, the wild parsnip (*Pastinaca sativa*) and its most important associated herbivore, the parsnip webworm (*Depressaria pastinacella*), are thought to be engaged in coevolution mediated by the evolution of furanocoumarins and the insect's detoxifying mechanisms. May R. Berenbaum has documented genetic variation both in the production of furanocoumarins and in the webworm's ability to metabolize this group of plant toxins.

Quantitative genetics is also used to measure correlations between traits. The detection of negative genetic correlations is indicative of trade-offs between traits, such that selection for the increase in value of one trait leads to a decrease in value of the correlated trait. Tradeoffs are of particular relevance in explaining evolutionary constraints, and particularly why species are specialized. Pea aphid (*Acyrtosiphon pisum*) clones collected from two crop plants (alfalfa and red clover) exhibited higher fitness when reared on the plant from which they had been collected, suggesting local adaptation. The

negative genetic correlation in fitness across crops may constrain the evolution of generalist clones, as these would be outcompeted on either plant by crop-specialized clones.

Measurement of genetic variation and correlation between traits offers information on the genetic context in which selection can act. Correlations between traits and fitness suggest the form and direction of selection. In a greenhouse study, the wild parsnip exhibited a negative genetic correlation between concentration of several furanocoumarins and seed set, suggesting that the production of the chemicals may impose a cost to reproduction in the absence of the parsnip webworm. These negative correlations were not detected in the field, indicating that presence of furanocoumarins increases fitness in the presence of the herbivore. Ideally such studies are performed in a natural setting, as our ultimate interest is understanding how natural selection works in the wild, but one can use model systems in the laboratory, such as evolving populations of bacteria and bacteriophage.

Finally, studies of interacting species are commonly based on the analysis of single communities. However, most species are composed of many local populations, and increasing importance has been attributed to the geographical structure of species and their interactions. Across the distribution of an interaction one is likely to observe a mosaic of selection pressures as a result of variation in abiotic and biotic factors, and the particular demographic and genetic histories of local populations. Some localities may be coevolutionary hot spots, that is, sites of reciprocal coevolution, whereas in others selection may be unidirectional or act on neither species. The geographic variation in outcomes is further modified by gene flow among populations. Consequently, different degrees of coadaptation are to be expected among populations. Clearly our understanding of the dynamics of a species interaction requires the study of many communities and interpopulation processes.

A few cases that satisfy the requirements of long-term multipopulation studies have emerged recently and have reinforced our need for a *geographic mosaic theory of coevolution*. For instance, resistance and virulence structures of *Linum* and *Melampsora* (referred to earlier), studied in New South Wales, sometimes vary dramatically across populations and time. The frequency of susceptible genotypes of flax will affect the local frequency of a particular strain of flax rust, but additional factors were found to play a role, namely, drift, extinction, and migration from neighboring populations. The geographic structure of flax and rust proved to be an essential factor in explaining the persistence of the interaction.

Rates of Adaptation

Phylogenetic reconstructions and the fossil record provide some examples of ancient interactions between groups of organisms. Character mapping of feeding habits onto beetle phylogeny indicates that conifers and cycads are the ancestral host plants. The oldest fossils of herbivorous beetle taxa, from the Jurassic, are indeed ancestral forms of modern conifer and cycad feeders, suggesting that this association may have evolved 200 million years ago, making it the oldest insect/plant association known. Lichens, which are an intimate

association between fungi and green algae, may be 100–200 million years old. Yet how often do new interactions establish themselves, how rapidly do species adapt to one another, and does that process occur on a timescale that is relevant to ecological processes?

The evolution of interspecific interactions can occur very rapidly, that is, during the course of 100 years. Examples include cases where recorded changes in the environment led to measurable changes in phenotype. In 1977, the Galápagos Islands suffered a severe drought during an El Niño event, causing an increase in the median size of available seeds. During the same event, the medium ground finch (*Geospiza fortis*) suffered strong selection for an increase in bill size, as only larger-billed birds could effectively feed on the available large seeds. This morphological shift occurred in a single generation. Many cases involve species of animals and plants introduced into new habitats. Populations of the apple maggot (*Rhagoletis pomonella*) that fed exclusively on native hawthorn have in the course of the past 100 years become adapted to a novel host, the introduced apple. The loss of interaction-related adaptations has also been observed to occur on a short timescale. Within the course of a 34-year study, guppies (*Poecilia reticulata*) artificially introduced into drainages in Trinidad, where natural predators are absent, lost defensive antipredator behaviors exhibited in the source populations.

Although these examples unequivocally demonstrate that interspecific interactions can evolve rapidly, they do not provide examples of coevolution. Almost all examples describe the evolution of *one* species adapting to another, with little reference to reciprocal changes. One of the few exceptions is the effort to biologically control the rabbit (*Oryctolagus cuniculus*) in Australia. The introduction of the myxoma virus into Australia initially reduced the rabbit population drastically. Such strong selection led to the evolution in just a few generations of increased resistance in rabbits. This evolutionary change was accompanied by a decline in the virulence of the virus to an intermediate level. Although in this case evolutionary change was observed in both interacting species, this does not necessarily constitute a case of coevolution. The reduction in virulence did not occur as a result of changes in rabbit resistance, but rather because the initial strains of the virus were so virulent that they quickly killed the host, lowering the likelihood of transmission by the disease's vector. More recent data, however, seem to indicate that the initially more virulent strains are presently increasing in frequency, perhaps as a result of increased rabbit resistance.

Rapid evolution is not, however, unconstrained. Each species is influenced by its phylogenetic history, and even populations of the same species will possess different evolutionary potential. To grasp how often new interactions are formed, one needs to understand these constraints. Rapidly evolving interspecific interactions can potentially affect the dynamics of community structure. Models of community ecology should not rest on the assumption that evolutionary dynamics occur on a larger timescale that is irrelevant to ecological processes. But it has yet to be determined under which conditions coevolution drives community dynamics and whether it has a stabilizing role.

Competition Between Species

Hypotheses about the coevolution of competing species have long played a major role in both evolutionary biology and ecology. Most of the hypotheses are variations on the theme that species should evolve differences in resource utilization, thus reducing competition between them. For Darwin, the principle of “divergence of character” in response to competition, described in *The Origin of Species*, explained why an ancestral species should give rise to multiple, diverse descendant species. W. L. Brown and E. O. Wilson cited reduction of competition as a major cause of *character displacement*, the term they coined for a greater difference between sympatric than allopatric populations of two species. D. Lack and R. H. MacArthur provided famous examples of differences in diet and foraging behavior or trophic morphology among closely related species of birds, interpreting the patterns as stemming from avoidance of competition. G. E. Hutchinson cited instances of apparently constant ratios of the dimensions of trophic structures among sympatric congeners. MacArthur and R. Levins elaborated on this theme, developing a theory of limiting similarity that concerned the expected degree of niche differentiation among sets of potentially competing species, as part of a theory of the evolution of community structure that has had lasting influence. The importance of competition and of coevolution of competitors was the subject of vigorous debate in the 1970s and 1980s.

The most detailed recent models of coevolution of competitors (Taper and Case, 1992) assume that the size of a phenotypic feature, such as body size or beak depth, is correlated with the mean food type (e.g., prey size) that an individual uses. The evolution of the character, and thus of resource use, is modeled using quantitative genetic models for polygenic traits. (The character is approximately normally distributed, with specified additive genetic variance and heritability.) It is assumed that “a jack of all trades is master of none,” that is, that there exist trade-offs in adaptation so that each phenotype performs effectively over only a relatively small range of resources (its within-phenotype niche width, WPNW), and that a specialized phenotype (with smaller WPNW) is more efficient than a generalist. (For example, studies of finches have shown that the rate of energy intake from smaller versus larger seeds is greater for small-billed versus large-billed birds, respectively.) In the simpler models, the competitive effects of phenotypes on each other are symmetrical and are proportional to the degree of resource overlap, whether the phenotypes be the same or different species. Thus competition is more intense when two phenotypes are more similar.

The size–frequency distribution of resources is assumed to be unimodal. Thus the rarity of resources in the tails of the distribution selects against extreme phenotypes. Consequently, the mean phenotype of a solitary species evolves to match the peak of the resource curve. Frequency-dependent selection maintains variant phenotypes, each adapted to a slightly different resource. However, the higher WPNW is, the less genetic variation is maintained. Because of recombination among the many loci affecting the trait, the frequency distribution of phenotypes remains approximately normal. It does not necessarily fit the frequency distribution of resources, some of which may be underutilized.

When applied to two or more species, these models generally support earlier suppositions. In each species, phenotypes that do not bear the combined burden of interspecific and intraspecific competition have higher fitness. Hence, the species evolve so that their phenotypic means are spaced apart (character displacement). Moreover, the phenotypic variance within each species at equilibrium is somewhat smaller than in a solitary species. At equilibrium, some overlap remains in the species' resource utilization, for otherwise abundant food items of intermediate size would be left unused, creating selection for genotypes that can use them. Under some conditions, especially if two species initially overlap greatly in resource use, they may converge. Competitive exclusion, resulting in extinction, then becomes more likely. Moreover, if competitive effects are asymmetrical (e.g., if larger individuals reduce the fitness of smaller ones more than the converse), a species may converge toward another and "chase" it to extinction.

Facile invocation of evolutionary responses to competition to explain ecological patterns was severely criticized in the 1980s, resulting in more critical evaluation of evidence. Even under the new scrutiny, many data strongly support the theory of coevolution of competitors. For example, character displacement has been documented in many instances, such as sticklebacks in British Columbian postglacial lakes. Some lakes harbor two species, recently derived from a common ancestor, that differ in microhabitat and in morphological features associated with feeding. Other lakes have only one species, with intermediate behavior and morphology. Closely related sympatric species often differ more consistently than would be expected by chance. For instance, body size in bird-eating hawks (*Accipiter*) is correlated with average prey size, and throughout the world sympatric species of these hawks differ more in size than do random pairs of *Accipiter* species.

Such nonrandomness of sympatric assemblages might arise from either coevolution or ecological assembly (colonization followed by extinction of excessively similar species). Phylogenetic analyses of anoline lizards in the West Indies have provided evidence of both processes. Many islands in the Lesser Antilles have both a large and a small species. These form distinct clades, so there is no evidence that the size of any one of these species have evolved in response to a sympatric congener. But each of the Greater Antilles has a monophyletic group of species that differ ecologically and morphologically from each other in a parallel pattern that is almost the same on each island. For example, each island has at least one species of "trunk anole," one "twig anole," and one "crown giant." Coevolution has taken much the same historical course in each case.

Release from competition is thought to have important evolutionary consequences. "Ecological release" at a microevolutionary level is illustrated by cases in which only a single member of a genus occurs in a region, and there occupies a broader ecological niche than do species that coexist with congeners elsewhere. The single species of finch on isolated Cocos Island, northeast of the Galápagos archipelago, feeds on a much wider variety of items than does any of its many Galápagos relatives, and the sexual dimorphism in beak size and forging mode is greater in the Hispaniolan woodpecker than in its continental relatives that are sympatric with other woodpecker species. At a macroevolutionary level, the spectacular diversification of African lake cichlids in the virtual

absence of other fishes, the explosive diversification of mammals after the K-T mass extinction of large reptiles, the flowering of modern turtles after the extinction of primitive amphielydian turtles, and many other examples are thought to show how diversification can be released when incumbent competition is alleviated.

Responses to Common Predators

Escape Space and Divergent Defenses

Competition is not the only possible explanation of resource partitioning and community assembly. For instance, species may interact indirectly via a shared predator. Predator density is highest where prey species coexist, and consequently a particular prey species will be maintained at lower density if it coexists with other prey species than if it is the sole victim. This form of predator-mediated *apparent competition* creates a pattern identical to that of direct competition. Coexistence is possible if prey species partition the resource they compete for, in this case an ecological space of reduced predation, known as an *escape or enemy-free space*.

Predators tend to increase their search intensity with increasing densities of prey. Search behavior can be improved by specialization in a foraging strategy, for instance, by attacking prey of a certain shape (i.e., similar search image) or prey that occupy particular sites, regardless of whether they belong to the same or different species. If faced with a diversity of prey patterns, they are most likely to form a search image for the most common pattern. This has been demonstrated for many bird and mammalian predators that use primarily visual cues. For example, if wild thrushes are presented with different combinations of two morphs of the snail *Cepaea nemoralis*, they will invariably preferentially attack the most common morph. The rarer individuals that differ from the ecological characteristics that the predator is attuned to will consequently experience lower predation rates. Such frequency-dependent selection within species, or *apostatic selection*, could lead to the divergence among prey species and an eventual increase in the diversity of forms and coloration patterns, that is, *aspect diversity*.

Evidence for this process is mostly circumstantial. R. E. Ricklefs and K. O'Rourke compared morphology, color, and behavioral characteristics of the moth species of a tropical and two temperate communities. Despite a higher number of moth species in the tropical site, the average similarity among moths within a community was the same in all three sites. They suggested that predation influences competition among moths for "escape space," limiting the similarity of appearance in different moth communities. *Cepaea nemoralis* and *C. hortensis* are both polymorphic for shell coloration pattern, and they share similar patterns. Bryan Clarke studied mixed colonies of *Cepaea* and found a negative correlation between the frequencies of visually similar shell patterns in the two species.

Mimicry

Another form of coevolution among prey species subject to common predators is the coevolution of mimicry. Two

common forms of mimicry are typically distinguished. Batesian mimicry refers to the convergence of palatable mimic species on distasteful models. Predators learn to avoid certain prey shape and color patterns they experienced as distasteful and mimics of such patterns can profit from this aversion. Monarch butterfly larvae, *Danaus plexippus*, feed almost exclusively on milkweed, from which they sequester cardiac glycosides. These toxic compounds are retained in the adult and vertebrate predators quickly learn to avoid both monarch adults and the more palatable mimetic viceroy butterfly, *Limnitis archippus*. Cleaner fish provide a variation on Batesian mimicry. In coral reefs in the Pacific, many fish allow cleaner fish, such as the sea swallow (*Labroides dimidiatus*), to feed on parasites on their bodies and even in the interior of their mouths. The sabre-toothed blenny (*Aspidontus taeniatus*) mimics the white-and-black-striped coloration and swimming pattern of *Labroides*. By taking advantage of the passive behavior of fish toward the model, it is able to approach fish and bite off pieces of tissue. *Labroides* and *Aspidontus* show parallel variation in color patterns across different geographic areas, which strongly suggests that indeed the mimic is converging on the model. It is a matter of discussion, however, whether mimics will instill evolution in the model, which might be expected to evolve differences that lessen the resemblance.

Müllerian mimicry refers to the convergence toward a similar pattern among unpalatable species. Faced with several undesirable species that look alike, a predator must learn a lower number of patterns to avoid. Evolution in all prey species leads toward a common pattern, and so warrants the designation of coevolution. One of the most striking cases of Müllerian mimicry, mentioned earlier, is the convergence between the neotropical butterflies *Heliconius erato* and *H. melpomene*. Despite differences in life history, these species share a common wing color pattern that varies geographically in parallel. One of the species, *H. erato*, is usually the most abundant where both species co-occur, raising the possibility that parallel evolution occurred by mere convergence of the rarer *H. melpomene* toward a common model. However, comparison between sympatric and allopatric populations of *H. erato* in Central America revealed that the width of the *H. erato* yellow hind-wing bar converges upon that of *H. melpomene* when in sympatry, suggesting that both species converge on each other.

Enemy–Victim Interactions

The general heading of enemy–victim interaction includes a variety of antagonistic interactions, ranging from those in which the enemy (or predator) usually kills several individuals (prey) to sustain itself, to scenarios in which the enemy (or parasite) restricts its negative effects to one victim (host) during most of its lifetime. The interaction between plants and herbivores is multiform, depending strongly on the herbivore taxon, and does not conform neatly to the previous division. Herbivores can be more akin to predators or parasites depending on whether they consume several individuals, as do seed harvesters, or complete their life cycle on a single plant, as do many leaf-feeding insects. They may also be quite unlike either category, as are many grazers and browsers that feed on parts of many individual plants without necessarily killing any

of them. Differences in the degree of specialization of the enemy and victim may enhance the asymmetry of the interaction. Most plants, for instance, are attacked by numerous herbivores and parasites, yet many of their enemies are relatively specialized on particular plant taxa. These distinctions and characterizations are relevant as the nature of the interaction determines the selection pressures imposed on both species, and the resulting coevolutionary process.

Enemy–victim coevolution has been envisioned as an arms race in which the exploiter evolves offensives that increase the strength (i.e., frequency, intensity) of the interaction, and the victim evolves counterdefenses to decrease it. In predator–prey interactions, for instance, one would focus on traits that in some way affect the predator's functional response, that is, its rate of predation. This includes everything from the predator's detection ability and pursuit speed to the prey's aposematic or cryptic coloration and escape speed. An *evolutionary arms race* would correspond, for instance, to a continuous improvement of a prey's escape speed and the predator's pursuit speed.

Clearly there are limits to such continuous escalation. There are physical limitations to improving an organism's features, for example, to how fast an animal can run. Furthermore, investment in an interaction-related trait may imply costs. Development of the trait may require resources that could otherwise be invested in reproduction and other functions. For instance, elaborate morphological defenses (e.g., a thick shell or thorns) may imply an *allocation cost* expressed as a slower growth rate. Chemical defenses can act as feeding deterrents, but at high concentrations they may be autotoxic, implying a *physiological cost*. Additionally, some chemicals that act as deterrents toward generalists attract specialist enemies. *Ecological costs* produced by such genetic correlations limit a victim's potential to adapt to its complete array of enemies. Traits tend to affect more than one function of the organism, and a compromise must be reached between its role in the different functions. For instance, Geerat Vermeij suggests that such an adaptational dilemma could have been responsible for the extinction of most ammonite cephalopods. The external shell of cephalopods, other than providing passive protection, also affects the speed of locomotion and the ability to compensate for changes in pressure during vertical movements. Toward the end of the Cretaceous, as predation and competition became more intense, no further improvement in these functions could be reconciled by evolution of the shell.

Theoretical work has shown that the existence of costs and density dependence (the effect of a species' density on fitness of an individual of that species or of an interacting species) can hamper the occurrence of continuous reciprocal responses implicit in an arms race. Neither the prey nor the predator population is expected to always increase its investment in predation-related traits as a response to an increased investment by its partner. On the one hand, depending on the shape of the predator's cost–benefit function, the benefits reaped by an individual predator by investing more in predation can be insufficient to compensate for any additional costs. The predator's capture rate may remain unaltered if the evolution of greater prey elusiveness is accompanied by an increase in prey density. On the other hand, models have shown that the evolution of greater prey-capture abilities can lead to a decrease in the predator's equilibrium population size as a result

of overexploitation of prey (Abrams, 1990). A smaller predator population can imply reduced selection for antipredator traits, and if the costs of defense become a more important selective factor than predation, the prey population may evolve a lower level of defense. So rather than a protracted arms race, one might expect enemy and victim to coevolve toward an intermediate stable state.

The models referred to previously focused on character values and population dynamic parameters. A different class of models focuses on the genetics that underlie interaction-related characters, while usually ignoring changes in population densities. For example, gene-for-gene models of host-parasite interactions examine changes in genotypic frequencies at a virulence locus in the parasite and at a resistance locus in the host. Coevolutionary cycles are expected under a broad range of conditions. As the frequency of a virulent genotype increases, selection for resistant host genotypes becomes more intense. Frequency-dependent selection will generate fluctuations in genotypic frequencies, and both populations will remain polymorphic. Some polygenic models also produce stability, as either stable limit cycles or equilibrium points, particularly if the additive genetic variances of the characters are high in both interacting populations. Stability is most likely if the victim has a larger genetic variance and is under stronger stabilizing selection than the enemy is. A higher additive genetic variance allows the prey to respond to selection more rapidly than the predator.

The "Red Queen" model extends the notion of evolutionary arms race to the level of a community. According to these models, evolution of co-occurring species can lead to the continuous deterioration of a species' environment, forcing it to constantly evolve just to avoid extinction. The name owes its origin to the character in Lewis Carroll's *Through the Looking Glass* who explained to Alice that one must run as fast as possible just to stay in place. Analogously, a community at evolutionary equilibrium determined by the Red Queen principle contains a set of interacting species continually coevolving at rates that exactly balance each other. It has been hypothesized that Red Queen coevolution has selected for recombination and sexual reproduction, as only those populations with available genetic variation could have sustained continuous coevolution for extended periods.

The most plausible models of enemy-victim coevolution predict either evolution to an equilibrium or an oscillatory coevolutionary "chase" (rather than indefinite escalation of offensive and defensive properties). The clearest evidence for these models' predictions should come from direct observation of long-term coevolution, which to date has been possible only with laboratory cultures of organisms with very short generations, such as bacteria and virulent bacteriophage. The most extensive coevolution observed in such experiments consisted of fixation of a resistance mutation in the bacterial population, then of a countervailing "virulence" mutation in the phage, and finally of a second resistance mutation in the bacteria, resulting in stable coexistence and an apparent genetic equilibrium. The resistance mutations of the bacteria carried costs that reduced fitness in the absence of phage, but evolution at modifier loci later reduced the cost. The failure of the phage population to coevolve greater virulence was attributed to architectural constraints on these very simple organisms.

Although data from natural populations reveal little about the long-term dynamics of coevolution, they do show that it occurs. Perhaps the most famous instance is the evolution of greater resistance of rabbits to myxoma virus, released as a rabbit-control measure in Australia. This was coupled with evolution of somewhat lower virulence in the virus (see earlier discussion). Comparisons among geographic populations and species also provide evidence of coevolution. Parasites are commonly better adapted to their local host population than to other populations, as in the case of a microsporidian that infects the cladoceran *Daphnia magna*. Brood-parasitic cuckoos are polymorphic for egg color: females generally specialize on one or another species of host, and lay eggs that mimic those of the favored host. Some species of birds, especially those most frequently parasitized, reject foreign eggs if they can detect them. In some such species, rejection behavior is stronger in populations that experience parasitism by cuckoos than in those that do not. Thus, both the cuckoo and some of its hosts have evolved responses to the interaction.

Geographic populations of interacting species sometimes vary in parallel, although the causes of variation can be difficult to identify. For example, the parsnip webworm (*Depressaria pastinacella*), the sole specialized herbivore that has accompanied wild parsnip (*Pastinaca sativa*) from Europe to North America, exerts selection on the plant's profile of several toxic furanocoumarins. Variation in furanocoumarin profile among populations of the plant is paralleled by variation in the differential capacity to metabolize these compounds in the associated populations of webworm. Although geographic variation in the insect is surely an adaptation to local plant characters, it is harder to show that variation among plant populations has evolved in response to selection by the insect.

Examples of adaptations of predators to prey or of the reverse abound. Yet in few instances has it been demonstrated that these adaptations have evolved in response to any one species. Many characteristics have a similar effect on several or many species of antagonists, and probably represent diffuse coevolution. For instance, the "Mesozoic marine revolution," in which the evolution of diverse shell-crushing crustaceans and fishes was mirrored by the evolution of spines, thicker shells, and other defensive features in many lineages of molluscs, doubtless represents diffuse coevolution. It is difficult in such cases to show that an evolutionary change in any one species stimulated coevolutionary change in another.

Special Features in Parasite-Host Coevolution

Several topics loom large in the study of parasites and hosts that seem to play a lesser role in coevolution of animal predators and their prey.

Gene-for-Gene Systems

Whereas features that mediate predator-prey interactions, such as size, trophic structures, and cryptic coloration, are usually polygenic (quantitative) characters, specific loci for resistance have been identified in several species of plants. For each such resistance gene, a corresponding locus in a fungal

pathogen confers “virulence,” meaning here the ability to attack and develop on a host with a specific resistance allele. (Most well-studied gene-for-gene systems involve crop plants, which has led some authors to suggest that resistance genes with large effects may be a result of the methods used to breed for resistance.) In the absence of pleiotropic costs, resistance alleles at all loci would be fixed in the host population and virulence alleles would be fixed in the parasite. If these alleles do have costs, then frequency-dependent selection can result in long-term fluctuations in allele frequencies, so that each species remains polymorphic and is continually adapting to the changing genetic constitution of the other. (This would be a clear instance of the Red Queen principle.) Populations of Australian wild flax differ in the frequencies of phenotypes resistant to various strains of flax rust, and associated rust populations likewise vary in virulence. The variation among populations may be an effect of Red Queen dynamics.

Selection for Sex

The supposition that parasite populations continually evolve has suggested to many authors that a major advantage of recombination and sexual reproduction may reside in the ability to generate novel, parasite-resistant genotypes. In a species of freshwater snail, for example, sexually reproducing females are more frequent than parthenogenetic females in habitats where the risk of infection by trematodes is greatest. Furthermore, among the several theories of sexual selection by female choice is the proposal that it is advantageous for females to choose males whose elaborate ornaments and behavior indicate that they are not debilitated by parasites, and thus are likely to father parasite-resistant offspring. Evidence from a few studies has been interpreted as support for this hypothesis, illustrating the broad ramifications that coevolution may have.

Evolution of Virulence and Avirulence

Often, though by no means always, parasites have less virulent effects on their normal host species than on novel, recently invaded species of hosts. This pattern might result from (1) evolution of resistance in a host species, (2) extinction of highly virulent species of parasites (“species selection”), because they drive their hosts to extinction, and/or (3) evolution within parasite species toward lower virulence. The evolutionarily naive often do not distinguish between the latter two causes, and imagine that parasites evolve avirulence because this will safeguard the host population and thus the perpetuation of the parasite species. However, natural selection is not prescient, and selection within populations can easily lead to fixation of “selfish” genotypes that enhance the risk of extinction. Evolution of the level of virulence depends on many factors.

For a parasite such as a virus, bacterium, or protozoan that reproduces on or in its host, each individual host carries a temporary group of parasites. Consider first a case in which each host carries only a single, clonally propagating parasite genotype. The fitness of this genotype is measured by the number of uninfected hosts it infects, relative to other genotypes. This number is often proportional to the number of

offspring produced within the host and capable of transmission. But greater numbers of parasites take a greater toll on a host, resulting in greater virulence. The fitness of a parasite genotype is thus set by a balance between the rate of reproduction within the host and the reduction in transmission due to death or debilitation of the individual host. If a parasite population evolves less than maximal virulence, it is only because this enhances transmission of progeny to new individual hosts, not because it preserves the host population for future use.

The optimal level of virulence depends partly on the mode of transmission, especially whether it is mostly vertical (from parent host to offspring) or horizontal (as in sexually transmitted parasites). The transmission rate of a vertically transmitted parasite is directly proportional to the number of offspring of its carrier, so such parasites should be relatively benign. However, a horizontally transmitted parasite, given opportunity for transmission, does not profit from its host's further survival or reproduction. Many such parasites kill their hosts (e.g., baculoviruses of insects) or castrate them (e.g., some plant-pathogenic fungi).

The evolution of virulence is still more complex if individual hosts are typically coinfecting by multiple genotypes of the parasite. *Within* each host, the genotype with highest growth rate r (and highest virulence) has an advantage, but if individual hosts bearing this genotype die before transmitting it, groups of parasites dominated by less virulent genotypes will transmit the most offspring. Thus group selection favors lower virulence, and individual selection favors higher virulence. At equilibrium, the level of virulence is likely to be the higher than in the case of singly infecting parasites. Comparison of the virulence of species of nematodes that infect fig wasps either singly or multiply has supported this theory, and phage in laboratory cultures evolved lower virulence if they were vertically than if they were horizontally transmitted (Bull, 1994).

Special Features in Herbivore–Plant Coevolution

Resistance, Tolerance, and Overcompensation

Herbivore impact on plant fitness can be intense, imposing selection for traits that reduce the effects of herbivory. One class of traits simply reduces the incidence of herbivory by escaping herbivores in space and/or time, that is, by decreasing the plant's “apparency.” The idea is that abundant, long-lived plants in communities of low diversity will be more easily tracked down and fed upon by herbivores than ephemeral plants that establish short-lived populations in more diverse communities. Size of the plant may also be a factor, as small plants with simple architecture generally have lower insect diversity, perhaps by offering little protection to insects. Consistent with this hypothesis is the observation that among Capparales in Morocco, less damage by pierid butterfly larvae is incurred by species that fluctuate more in density. This suggests that greater constancy in population size and density, that is, greater predictability and apparency, increases the likelihood of herbivory. Fluctuations in density could, however, be a result of adaptation of germination to specific

environmental cues or other factors rather than pressures from herbivory.

Most plants must deal with the presence of herbivores, and possess a variety of mechanisms that either reduce herbivory (*resistance*) or ameliorate its effects (*tolerance*). The ability to tolerate damage, that is, to suffer a reduced impact of damage on fitness, depends both on extrinsic factors, such as resource availability, the timing of herbivory, and the parts affected, and on characteristics of the plant. Thus it is thought that plants with intrinsically higher growth rates, storage capacity, or higher number of active meristems will have greater opportunity for regrowth in face of biomass loss to herbivory. It is as yet unclear whether these traits are adaptive defenses or whether they evolved because of other selective forces, such as competition and resource assimilation.

Some experiments have suggested that under ideal conditions, damage at certain phenological stages and the presence of abundant resources could render plants more fit than had they not incurred damage, that is, they would overcompensate. For example, artificially damaged scarlet gilia (*Ipomopsis aggregata*) produced approximately twice as many flowers and fruits as undamaged plants. The root biomass of clipped plants was greater than that of controls, suggesting that by increasing root size plants were able to take up the extra nutrients necessary for the overcompensation response. This implies that herbivores would benefit plants by feeding on them. There is controversy over the design and results of these experiments, and overcompensation has not been observed in enough species to be considered a general phenomenon.

Greater attention has been given to plant resistance, namely, to mechanisms that actively repel herbivores or that make the plant unpalatable or undesirable. Resistance mechanisms differ with respect to when they are expressed: many defenses are constitutive, that is, expressed regardless of herbivore presence, whereas others are absent until induced in the presence of herbivores. Induced responses curtail the costs associated with defenses, as these are incurred only when strictly necessary.

Some plants have morphological defenses, such as hard seed coats, thorns, or stinging hairs. However, a central role in defense has been attributed to secondary metabolites. These chemicals play no part in primary metabolism and groups of compounds are usually restricted to a few plant families. They have been found to affect herbivore behavior by decreasing a herbivore's feeding rate, deterring oviposition, slowing development, and reducing fecundity. Yet many of these compounds have also been found to affect bacteria, fungi, viruses, other plants, and other herbivores. Secondary compounds might just as well be an adaptive defense to these organisms, or even serve other ecological or physiological functions (e.g., UV protection, drought tolerance). Convincing evidence that insects are a driving force in the evolution of plant chemical defenses comes from studies that compare the pattern of natural selection on putative resistance factors in the presence and absence of herbivores. For example, in the presence of herbivores a population of *Arabidopsis thaliana* was shown to be under selection for increased levels of mustard oils (or glucosinolates) and trichome densities.

In contrast to resistance, plant tolerance does not affect the performance or fitness of the herbivore. Herbivores will not be under selection pressure to overcome this plant defense and so coevolution should not be expected, unless resistance and tolerance are correlated. Theoretical models do indeed predict a trade-off between these two forms of defense, but the limited evidence so far is inconclusive.

Specialist and Generalist Herbivores

Most herbivorous vertebrates and many insects are generalists, feeding on plants in many families. A more specialized diet, of plants in only a single family, genus, or even species, characterizes the majority of herbivorous insects and a few vertebrates (such as the koala, a specialist on *Eucalyptus* foliage). The advantages of a broad diet seem clear: an individual can feed despite spatial or temporal variation in the availability of any one food type. Theoretically, the possible advantages of specialization are clear, but evidence is often more ambiguous.

Commonly, closely related species of insects specialize on different plants. Assuming their common ancestor fed on one or more of these plants, the problem is to explain why some of its descendants, instead of expanding their diet, abandoned their ancestral host to which they were presumably well adapted in favor of new hosts. Several ecological advantages of such a switch have been suggested. The new host might provide escape from predators or parasites. Certainly specialization is maintained, if not originally caused, by the protection that many insects, such as milkweed-feeding monarch butterflies, gain by sequestering defensive plant compounds. Competition for resources, as we have noted earlier, may also select for specialization. In many species, mating occurs only on the host plant, and use of a single host may be the most reliable way to find mates. Host specialization will then be a consequence of positive frequency-dependent selection. There is indirect evidence for each of these hypotheses.

The most general explanation for specialization is likely to be trade-offs in the ability to find, handle, digest, or detoxify different kinds of plants. The secondary compounds that characterize higher taxa of plants are thought to play an especially important role, since many are toxic and/or deter feeding by nonadapted insects. Conversely, host-specific insects typically use some such compounds as feeding or oviposition stimuli. The hypothesis that related specialist insects usually feed on related plants because of the plants' chemical similarity has been supported by a study of *Blepharida* flea beetles: the beetles' phylogeny is more closely mirrored by chemical similarity than by phylogenetic affinity among the species of their *Bursera* host plants.

Tests for trade-offs have had mixed results. There is little evidence that closely related generalist and specialist species differ in their efficiency of digestion of plant species that they both naturally feed on (Futuyma and Wasserman, 1981). There is some evidence that specialist species can find and recognize host plants faster than generalist species, owing to properties of the nervous system, and abundant evidence that closely related species are physiologically better adapted to their own than to each other's host plant species. However,

since such differences may have evolved after these species became specialists, most research on trade-offs has compared genotypes within species. Only a few such tests have found clear evidence of trade-offs; different clones of pea aphids, for example, have high fitness on either pea or alfalfa. In no case is the biochemical or physiological basis for such trade-offs fully understood.

Mutualism

In a mutualistic interaction, individuals of each of two species obtain a fitness benefit from the interaction between them. Long-term physical associations are referred to as symbioses. These include endosymbioses, in which microorganisms such as bacteria reside within their hosts. In some cases, endosymbionts have become, in effect, part of the host. Mitochondria and chloroplasts, for example, evolved from endosymbiotic bacteria early in eukaryote evolution.

Some mutualisms have doubtless evolved from casual, fortuitously beneficial interactions; such may be the origin, for instance, of the nectar glands of many plants that attract generalist ants, which attack herbivores and other intruders. Some such mutualisms have become obligate, as in the case of some *Pseudomyrmex* ants that inhabit and defend only certain species of *Acacia* trees that provide food bodies and special domiciles. In many cases, especially symbioses, mutualisms have arisen from parasitic interactions; for example, a complete spectrum from parasitism to mutualism is found in endophytic fungi (Clavicipitaceae). The conditions that favor evolution of parasitism into mutualism are much the same as those favoring the evolution of avirulence (see earlier). Specifically, the fitness of vertically transmitted symbionts depends on the fitness of their hosts, so a benefit provided to the host will enhance the symbiont's fitness. Even without vertical transmission, long-term (e.g., lifelong) association between individual partners satisfies the conditions for "reciprocal altruism." The survival and reproduction of a colony of *Acacia*-dwelling ants depends on the health of its host tree, so it pays to defend it, just as the fitness of the tree depends on nurturing its defending ant colony.

Many mutualisms are rather nonspecific, in that at least one of the species of partners holds a mutualistic relationship with several or many species. Most mycorrhizal fungi, for example, are not highly host-specific, and most species of pollinating or seed-dispersing animals visit many species of plants. There are, however, some exceptions, such as the fig wasps, each species of which develops as a seed predator of one of the several hundred species of fig and is the sole pollinator of that species. The vertically transmitted bacterial endosymbionts (*Buchnera*) of aphids are so intimately tied to their hosts that the phylogeny of the bacteria mirrors faithfully that of the aphids. Unique associations of lineages of aphids and bacteria have persisted for more than 100 million years.

Mutualism can generally be viewed as reciprocal exploitation. Mutualists do not provide benefits to their partners out of altruism; the benefit is either wrested from them (e.g., pollen consumed by pollinating bees) or it is a "payment" that ensures a reciprocal benefit. Thus potential conflict pervades most mutualisms, for selection often favors "cheater"

genotypes that do not repay the benefit they receive. For instance, bees often rob nectar by chewing through the bases of flowers, so that they do not pollinate. Many orchids deceive pollinating insects, providing neither nectar nor consumable pollen, but instead produce scents that mimic the insect's sex pheromone and induce "pseudocopulation" by male insects that effect pollination. Some orchids produce no reward whatever. Selection for cheating can destabilize a mutualistic relationship. For example, yucca moths (*Tegeticula*) oviposit in the ovaries of *Yucca*, where the larvae feed on some of the developing seeds. Most species of *Tegeticula* stereotypically (and "carefully") place pollen on the stigmas of flowers in which they lay, and so both the host plant and the moth's offspring benefit. However, several lineages of "cheater" *Tegeticula* have evolved from pollinating ancestors; they do not pollinate, but lay eggs in flowers that have been pollinated by those species that do.

Major Consequences of Coevolution

If it is difficult to document and characterize coevolution between pairs or among small numbers of species, it is harder still to demonstrate the effects that coevolution has had on the properties of communities, ecosystems, or the history of biological diversity. For the most part, questions on so grand a scale have, so far, only tentative or even speculative answers.

Phenotypic Diversity

Although no quantitative data are available, coevolution, or at least adaptation to interspecific interactions, has unquestionably enhanced the phenotypic diversity ("disparity") among species. The diverse trophic structures displayed by related species of fishes, birds, and other animals partly reflect adaptation to the characteristics of the different arrays of prey species on which they feed, and partly arise from selection due to interspecific competition, resulting in divergence and specialization in resource use. The diverse morphologies in such adaptive radiations as the African lake cichlids illustrate that ecological and morphological diversification of a clade may be promoted by competition among its member species, but may be constrained by competition from members of other clades, until such competition is relieved.

Predation and parasitism have doubtless enhanced phenotypic diversity among prey. There is much circumstantial support for Ehrlich and Raven's hypothesis that chemical diversity among plant taxa has been driven by herbivores (and, we would add, pathogens). Intraspecific genetic diversity at major histocompatibility loci has almost certainly been maintained by selection imposed by pathogens, and the extraordinarily complex immune system of vertebrates is testimony to the potent selection that pathogens generate. The Mesozoic evolution of shell-crushing predators called forth an immense proliferation of defensive features in the shells of molluscs.

The cooperation and conflict inherent in mutualism have likewise had immense effects on phenotypic diversity. The mycetocytes of aphids, the light organs in some fishes and

cephalopods, and the root nodules of legumes are among the many special structures that house symbiotic bacteria. The phenotypic diversity of the Orchidaceae, the largest family of plants, lies largely in the extraordinary variety of flower forms that attract and manipulate diverse pollinating animals.

Although such examples provide undeniable evidence that biotic interactions have had great evolutionary consequences, phenotypic disparity has seldom been measured. Moreover, although the role of interactions in these examples is obvious, the importance of reciprocity (the “co” in coevolution) is not. Rigorous tests of the effects of coevolution remain to be done.

Species Diversity

Variation in species diversity among clades, communities, ecosystems, and biomes and through geologic time is affected by many factors. The relative importance of coevolution on rates of speciation and extinction, which together determine diversification rate, is unclear. Only in exceptional cases, such as the divergence of figure and their species-specific agaonid pollinators, is it likely that coevolution directly induces speciation, that is, reproductive isolation. It has often been suggested that animal-mediated pollination and seed dispersal may enhance rates of plant speciation by establishing reproductively viable isolated populations. However, species diversity of angiosperms is only slightly greater in animal- than wind-pollinated families, although it is greater in families that include both biotic and abiotic seed dispersal than in families that use one mode exclusively.

In principle, extinction rates can be increased or decreased by coevolution, although either is very difficult to document in practice. If coevolution has effected a net increase in diversification rate, it has probably done so chiefly in three ways: (1) by shifts in resource use, thus reducing competition; (2) by evolutionary escape from predation, followed by radiation; and (3) by evolution of specialized predators, parasites, and mutualists following the evolution of new prey or hosts. That is, diversification of one group of organisms begets diversification of others, as Ehrlich and Raven postulated for plants and herbivorous insects.

These hypotheses are supported by some modest evidence. Farrell *et al.* (1991) found that clades of plants with canals that deliver defensive latex or resin to sites of herbivore attack are consistently more diverse than their sister groups that lack these features. Similar sister-group comparisons among insects showed that the evolution of herbivory has consistently been followed by greater diversification. However, it is not known if the diversity of herbivorous insects has been enhanced in clades that have adapted to chemically novel, diverse plant clades, as Ehrlich and Raven proposed. In western Europe, the species richness of aphids and certain other insects that feed on different plant families is correlated with the number of species of plants in the family. Whether or not such a correlation holds on a global scale is not known.

Community Structure

The convergent evolution of ecologically “equivalent” species, such as many Australian marsupials and their placental

counterparts in other regions, suggests that independently evolving communities might converge toward similar structure. Certainly, properties such as vegetative morphology and the architecture of vegetation converge; for example, “Mediterranean” vegetation (chaparral, matorral, maquis) is dominated by sclerophyllous, small-leaved shrubs in several parts of the world. Such similarities, however, arise simply from each species’ independent adaptation to physical environmental factors. Whether or not community properties such as stability, food-web structure, or species diversity converge as a result of coevolution is a different, much more difficult question. Simple models of interspecific competition and of food webs suggest that the coevolutionarily stable equilibria might be rather few, so that coevolution might yield some predictable structure (MacArthur and Levins, 1964). Whatever the ideal applicability of these models might be, however, the opportunity for such pervasive effects of coevolution may generally be rather slight. Gene flow among conspecific populations that interact with different ensembles of species may prevent finely tuned coevolution. Moreover, paleoecological studies have shown that throughout the Pleistocene, species have had highly individual histories of change in geographic distribution, so that many of today’s assemblages of species are very recent. Except for specialized associations, as of host-specific parasites that have moved about with their hosts, there has been little time for coevolutionary adjustments in many of today’s species assemblages. Nevertheless, paleontologists have documented rather steady levels of diversity at both global and local levels over vast periods of time (10^7 – 10^8 years), despite turnover of taxa (Jablonski and Sepkoski, 1996). These observations suggest that whatever convergence or constancy of community structure exists may be attributable more to purely ecological rules of community assembly rather than to coevolution.

An unusually clear example of convergent multispecies assemblages is provided by the anoline lizards mentioned earlier, which form monophyletic groups of morphologically and ecologically equivalent species on each of the Greater Antilles islands. However, similar habitats in different parts of the world generally are not very similar in species richness. For example, lizard diversity in Australia exceeds that in corresponding habitats in southern Africa. Nevertheless, in some instances variation in species richness among habitats shows similar patterns; lizards are more diverse in deserts than in wetlands in both Australia and Africa. Thus, habitats seem to have consistent effects on species coexistence, and perhaps on the evolution of resource partitioning (Ricklefs and Schluter, 1993).

Coevolution may also affect community properties such as stability, that is, the property of returning to equilibrium after a disturbance. The study of artificially constructed food webs has identified some patterns of interaction among component species that are conducive to stability. One such aspect is connectance, that is, the ratio of actual to potential interspecific links. High levels of connectance are associated with reduced stability, as a disturbance to one species will affect many other species in the community. Thus processes that reduce connectance, or generate compartments within a community, such as a subset of species that interact predominantly with one another, contribute to stability. To the

extent that coevolution between parasites and hosts and between plants and herbivores leads to increased levels of specialization (and thus compartmentalization), it can thus indirectly enhance community stability.

Glossary

Carrying capacity Maximum number of organisms that can be supported by a given habitat, based on the amount of resources available (such as food, nutrients, shelter, and space).

Exploitation competition Interaction among two or more species that use a common resource that is limited, in which one species benefits more than the other.

Interference competition Interaction among two or more species that use a common resource that is not limiting, in which one species is harmed by having its access to the resource restricted.

Resource partitioning Ecological arrangement in which two or more species use different, nonoverlapping resources in a given habitat, such as warblers foraging for insects in different locations within a tree or canopy.

Introduction

Interactions between species can be classified and defined in various ways. A very useful method of classification is to consider the effect that individuals of one species have on the population growth of another species and vice versa. We ask the question: In the presence of species A (+) does species B, (1) increase its numbers (+), (2) not change its numbers (0), or decrease its numbers (–) relative to when species A is absent (–)? The same question is asked of species A in the presence of species B. The answers are conveniently summarized in Table 1.

Because of the symmetry there are only six types of interaction. These are frequently called (1) 00 neutralism, (2) +0 commensalism, (3) +– predator/prey, parasite/host, or herbivore/plant interactions, (4) 0– amensalism, (5) –– competition, and (6)++ symbiosis. This article focuses on interactions of types (4) and (5) between individuals of different species. Amensalism is just an extreme example of asymmetric competition. This is competition, usually between a pair of species, in which the adverse effect of one species on the other is much greater than the reciprocal effect.

The negative effects on numbers are produced by individuals directly competing for essential resources (frequently food and space) that are in short supply. If the negative effect is caused by not getting enough of the limited resource, we call it exploitation competition. If the resource is not limiting, but individuals nonetheless harm each other in the process of obtaining it, we call it interference competition. An ecological situation can arise where two species appear to show the reciprocal negative effects associated with interspecific competition, but

this is in fact the result of predation by a third species. This is called apparent competition.

Consider the situation shown in Figure 1. A single species of predator attacks two species of prey. The predator/prey interactions are of – + type and therefore both species are adversely affected by the predator, and the predator is positively affected by both species of prey. This means that the positive effect that prey 1 has on the predator will, in turn, increase the negative effect on prey 2, and vice versa. The overall consequence of this is that there will appear to be a – – interaction between prey 1 and prey 2, even if they are not competitors for any essential and limiting resource.

How have ecologists studied competition in order to see the patterns that this ecological process produces? In general, there are four approaches (in common with all studies in ecology and, in fact, all science). These are (1) mathematical models (equations, graphs, or computer simulations), (2) laboratory experiments (laboratory models), (3) field experiments (field models), and (4) field observations. Each approach has its advantages and disadvantages. As you progress from (1) through (2) and (3) to (4), the unit of study becomes more complex but more realistic. Approach (1) helps us to understand a process (or system) and suggests what kind of (2) and (3) studies may be useful. In turn, these may direct us toward particular kinds of field observation that will help confirm or

Table 1 A classification of two species interactions

reject the patterns suggested by (1), (2), and (3). In fact the study of competition (its historical development) progressed in part from (1) to (4) and it is convenient to do the same in this account of interspecific competition. The remaining sections illustrate these four approaches with three examples.

Competition Models

The Lotka–Volterra Model

Vito Volterra was an Italian mathematician who, inspired by his son-in-law Umberto D’Ancona (an eminent hydrobiologist), published work on competitive interactions in the 1920s and 1930s. A. J. Lotka was an American mathematician who published on similar topics, also in the 1920s and 1930s. Their names are associated with a basic model of interspecific competition that has had a major impact on how ecologists think about this species interaction.

The Lotka–Volterra model of interspecific competition is based on two other models of population growth, the exponential growth model and the logistic sigmoid growth model. Let us look first at exponential growth, that is, when there is no competition of any kind. Under such conditions the rate at which numbers change with time (dN/dt) can be represented by a per capita (per head) rate of increase multiplied by the number of individuals (N) in the population. The rate of increase used is the intrinsic rate of natural increase (r) and is equal to the difference between the per capita birth rate and the per capita death rate. In mathematical symbols this can be written as

$$\frac{dN}{dt} = rN$$

In this simple model, the rate of increase does not change with density, that is, there is no density dependence and growth is unlimited. However, in most real populations, growth is a function of density (fN) and therefore the growth equation should be written as

$$\frac{dN}{dt} = rN(fN)$$

The simplest relationship that this function could have with density is shown in **Figure 2**. We know that the end points of this relationship are quite sensible. At very low population size ($N \cong 0$), fN must be $\cong 1$ because this would give unlimited exponential growth. At the equilibrium population size or

Figure 2 The density-dependent function used to produce the logistic equation.

carrying capacity, $N=K$, $fN=0$ and growth stops ($dN/dt=0$). Joining these two known points by a straight line assumes the simplest relationship possible and is not based on any empirical evidence. (Scientists, including ecologists, always develop their descriptions of the natural world by initially assuming the simplest relationships. Only when this proves inadequate do they make the explanation more complex. See Francisco Ayala’s experiments discussed in the section *Drosophila*.) The slope of the line is equal to $1/K$ and the equation of this straight line is therefore $fN=1 - N/K$. Substituting the value of fN into the previous equation now produces

$$\frac{dN}{dt} = rN \left(1 - \frac{N}{K} \right)$$

which is the well-known logistic equation that produces sigmoidal limited population growth. It is important to remember that the term in brackets represents intraspecific density-dependent regulation. The inhibitory effect of one individual on population growth is $1/K$ and the inhibitory effect of N individuals on population growth is N/K .

Now let us consider two species, each of which when living separately has its growth described by a logistic equation. However, when living together this logistic equation must be modified. In the following equations the two species are denoted by the subscripts 1 and 2. Let us consider first of all the population growth of species 1 when it competes with species 2. In terms of its own population growth, as described by the logistic equation, the inhibitory effect of one individual of species 1 on its own population growth is $1/K_1$, where K_1 is the carrying capacity of species 1. The inhibitory effect of every individual (N_1) of species 1 on its own population growth is therefore N_1/K_1 . If species 2 was identical to species 1 in its effect on the population growth of species 1, then we could simply write the effect of every individual of species 2 on the population growth of species 1 as N_2/K_1 . However, this is unlikely. It is more realistic to imagine that each individual of species 2 would have a greater or lesser effect on the population growth of species 1, and therefore we have to multiply N_2/K_1 by a constant that expresses this difference. This constant (usually called the competition coefficient and denoted by α_{12}) describes the relative effect of an individual of species 2 compared to an individual of species 1. If an individual of species 2 was identical (from an ecological point of view), then $\alpha_{12}=1$. Similarly, the effect of every individual of species 2 on its own population growth will be N_2/K_2 and the effect of every individual of species 1 on the population growth of species 2 will be N_1/K_2 multiplied by α_{21} (note the reversal of the subscripts).

To understand the competition coefficients (α_{12} and α_{21}) more clearly, let us take an imaginary example in which competition is solely for a single food resource. Let us imagine that two species of desert mouse eat seeds. Mouse 1 consumes 100 seeds per day, and mouse 2 consumes 200 seeds per day. In terms of resource units (seeds), an individual of species 1 = half an individual of species 2, or two individuals of species 1 = one individual of species 2. Therefore, $\alpha_{12}=2$ (the effect of adding one more individual of species 2 is like adding two more individuals of species 1) and $\alpha_{21}=1/2$.

We can now rewrite the two logistic growth equations for the two species (which incorporate intraspecific competition)

Figure 3 Graphical representation of the four predicted outcomes of the Lotka-Volterra model. Arrows indicate equilibrium points. The thin line=species 1 zero isocline and the thick line=species 2 zero isocline.

to take into account interspecific competition:

$$\begin{aligned}\frac{dN_1}{dt} &= r_1 N_1 \left[1 - \left(\frac{N_1}{K_1} \right) - \left(\frac{\alpha_{12} \cdot N_2}{K_1} \right) \right] \\ &= r_1 N_1 \left[\frac{K_1 - N_1 - \alpha_{12} \cdot N_2}{K_1} \right] \\ \frac{dN_2}{dt} &= r_2 N_2 \left[1 - \left(\frac{N_2}{K_2} \right) - \left(\frac{\alpha_{21} \cdot N_1}{K_2} \right) \right] \\ &= r_2 N_2 \left[\frac{K_2 - N_2 - \alpha_{21} N_1}{K_2} \right]\end{aligned}$$

This system of two species (the Lotka-Volterra model of two-species competition) will be at equilibrium when $dN/dt = dN_1/dt = 0$, that is, when both species are at their carrying capacities and population growth has stopped. Just considering for the moment species 1, this means that

$$r_1 N_1 \left[\frac{K_1 - N_1 - \alpha_{12} N_2}{K_1} \right] = 0$$

Since r_1 , N_1 , and K_1 cannot = 0 (mathematically possible but ecologically uninteresting if species 1 cannot reproduce, is not present, or cannot exist in that habitat), this means that for species 1, $K_1 - N_1 - \alpha_{12} N_2 = 0$ at equilibrium. Rearranging this equation we get $N_1 = K_1 - \alpha_{12} N_2$, which is the equation of a

straight line and is called the species 1 zero isocline. On a graph of the numbers of species 1 (N_1) plotted against the numbers of species 2 (N_2), it represents all those combinations of N_1 and N_2 for which the population growth of species 1 (dN_1/dt) = 0.

Following a similar procedure for species 2 will produce the species 2 zero isocline, which is $N_2 = K_2 - \alpha_{21} N_1$. On a graph of the numbers of species 2 (N_2) plotted against the numbers of species 1 (N_1), it represents all those combinations of N_1 and N_2 for which the population growth of species 2 (dN_2/dt) = 0.

There are four ways that these two straight lines can be placed on a graph of N_2 versus N_1 , and these are illustrated in Figure 3. These are known as phase-plane graphs/diagrams. Each point on the graph represents a joint density of the two species. To each point in this graph we can attach an arrow, or vector, whose length and direction will indicate the dynamics of the system. Below its zero isocline, a species can increase in numbers. Above its zero isocline, a species will decline in numbers. Exactly on its zero isocline, a species will neither increase nor decrease. This means that the four graphs predict different outcomes for interspecific competition. In (a) either species can win depending on which area between the zero isoclines the population trajectory reaches. This depends on starting numbers or relative growth rates (r_1 and r_2). The point where the two lines cross represents an unstable equilibrium point. In (b) the two species coexist at the values of

N_1 and N_2 were the two lines cross. This represents a stable equilibrium point. In (c) species 1 always wins and in (d) species 2 always wins.

Laboratory examples of one species winning (c and d) and coexistence (b) are provided by G. F. Gause's experiments (see *Yeast* and *Paramecium*). Examples of one species winning (c and d) and either species winning (a) are provided by T. Park's experiments (see *Flour Beetles*). It is important to make two comments about the Lotka-Volterra model. First, it contains hidden variables. The competition coefficients (α) are simply conversion factors to allow one species to be represented in the other species numerical equivalents. Species may compete for food and space and poison each other, but all of these mechanisms of competition are summarized and hidden within α . Second, because the real world (unlike most laboratory environments) is heterogeneous and patchy, even (a), (c), and (d) may result in coexistence. If within a habitat patch (a), (c), and (d) apply, there may only be one species per patch. But looking over many patches, both species will be seen to apparently coexist. This is the difference between what ecologists call local and regional coexistence.

What do these graphs in Figure 3 imply for competition and coexistence? Let us take graph (a) as an example (species 1 or species 2 wins depending on initial concentrations and/or the rates of increase). Using the end points of the lines, this graph can be defined as

$$\alpha_{12} > K_1/K_2 \quad \alpha_{21} > K_2/K_1$$

or by dividing the two sides of the left-hand inequation by K_1 and the two sides of the right-hand inequation by K_2

$$\alpha_{12}/K_1 > 1/K_2 \quad \alpha_{21}/K_2 > 1/K_1$$

In competition terms this means that the

effect of one individual of		species 2	species 1		species 1
species 2 on	>	on	on	>	on
species 1		species 2	species 2		species 1

In other words, each species reduces the dN/dt of the other species more than its own dN/dt , which we can summarize as

$$2 \text{ on } 1 > 2 \text{ on } 2 \quad 1 \text{ on } 2 > 1 \text{ on } 1$$

Interspecific effects for both species are stronger than intraspecific effects.

For graph (b) (coexistence) these inequalities are

$$2 \text{ on } 1 < 2 \text{ on } 2 \quad 1 \text{ on } 2 < 1 \text{ on } 1$$

which is the opposite of graph (a). Here each species reduces its own dN/dt more than that of the other species, and therefore interspecific effects for both species are weaker than intraspecific effects. This case has always intrigued ecologists, and the traditional explanation as to why interspecific effects for both species should be weaker than intraspecific effects is resource partitioning (see *Resource Utilization Curves*). However, there are other mechanisms that will produce this effect (see *The Aggregation Model*).

For graph (c) (where species 1 always wins) the inequalities are

$$2 \text{ on } 1 < 2 \text{ on } 2 \quad 1 \text{ on } 2 > 1 \text{ on } 1$$

which implies that the two species now do different things. Species 2 reduces its own dN/dt more than that of species 1, and species 1 reduces the dN/dt of species 2 more than its own dN/dt .

For graph (d) (where species 2 always wins) the inequalities are

$$2 \text{ on } 1 > 2 \text{ on } 2 \quad 1 \text{ on } 2 < 1 \text{ on } 1$$

and we have the opposite of graph (c).

Resource Utilization Curves

The Lotka-Volterra competition model predicts that two potential competitors will coexist if they each affect the growth of the other more than they affect their own growth. That is, intraspecific effects are greater than interspecific effects for both species. This is summarized by the inequations

$$\alpha_{12}/K_1 < 1/K_2 \quad \alpha_{21}/K_2 < 1/K_1$$

Traditionally this led to the concept of resource separation (different niches) as a mechanism of coexistence. Clearly, if two species use different resources they will interact (compete) only with their own species, and therefore the preceding inequalities will be true. But partial resource partitioning has also been used widely as an explanation for coexistence. Field observations in particular (see *Field Observations*) have frequently found partial resource separation between species and accumulated these differences over several niche dimensions to convince the reader that enough separation exists to explain the coexistence observed. Unfortunately, most of these field studies do not calculate α_{12} , α_{21} , K_1 , or K_2 and therefore we do not know if sufficient separation exists between the species to make $\alpha_{12}/K_1 < 1/K_2$ and $\alpha_{21}/K_2 < 1/K_1$. However, one attempt to quantify the amount of separation required is provided by a simple model, initially developed by Robert MacArthur (1972).

Imagine two species competing for a resource that can be visualized as varying continuously in one dimension, for example, insects or seeds of different sizes or foraging sites up a tree. Imagine also that the two species' utilization of this resource follows a unimodal distribution, with a preferred area of use in the center and less preferred resource items on either side. Figure 4 shows this idea for two species using a resource j , in which their resource utilization curves (u_{1j} and u_{2j}) are described by a normal distribution. Each species uses a

Figure 4 Resource utilization curves used in the MacArthur model. D is the difference between the means of the two normal distributions and σ is the standard deviation for the two normal distributions.

Figure 5 Relationship between α and the ratio d/σ predicted from the MacArthur model.

Figure 6 Foraging height of antbirds (Formicariidae). Notice that the means are separated by about one standard deviation, as predicted by the MacArthur model.

different part of the resource, with some overlap. The distance between the two means is d , and σ is the standard deviation. The two species are assumed to have the same carrying capacity and the intensity of competition is related to the area of overlap between the two distributions. With two normal distributions this is given by

$$\alpha = e^{-d^2/4\sigma^2}$$

and the relationship between α and d/σ is shown in **Figure 5**. For stable coexistence between two species, d/σ should be approximately greater than unity, that is, d (the distance between means) should be greater than σ (the standard

deviation of resource utilization). A field example that agrees with this amount of limiting similarity between species is provided by the foraging height relationships within antbirds (*Myrmotherula*), shown in **Figure 6**. Unfortunately, it has been pointed out that $d/\sigma > 1$, and promoting coexistence may be a property of this type of model only with a one-dimensional resource. With competition in several dimensions and alternative resource utilization curves, lower values of d/σ may be compatible with stable coexistence.

The Aggregation Model

Many insects exploit resources that are patchy, consisting of small, separate units, and that are ephemeral in the sense that they persist for only one or two generations. Such resources can include fruit, fungi, sap flows, decaying leaves, flowers, dung, carrion, seeds, dead wood, and small bodies of water held in parts of terrestrial plants (phytotelmata). This general view of insect ecology inspired the aggregation model of competition (Shorrocks *et al.*, 1984; Atkinson and Shorrocks, 1981), which allows a competitively inferior species to survive in probability refuges. These are patches of resource (a single fungus, fruit, etc.) with no or a few superior competitors that arise because the competing stages (usually larvae) have an aggregated distribution across the patches. These probability refuges are a permanent feature of such systems because patches, such as fungi, are ephemeral and aggregation increases mean crowding. Regional population density is limited by strong intraspecific competition in patches with high local density whereas low-density patches still exist (e.g., population size within a wood is limited by high density in some fungi, whereas other fungi still contain no or a few individuals). As with resource partitioning, coexistence is promoted because aggregation of the superior species increases its intraspecific competition and reduces interspecific competition.

In the aggregation model, the eggs of both insect species are independently distributed over the patches according to a negative binomial distribution, which has an exponent, k , inversely related to the degree of intraspecific aggregation. The use of the negative binomial and the assumption of independence have been justified for drosophilid flies. In the first version of the model, the parameter k (level of aggregation) was constant and independent of density. This is not valid for real populations, but relaxing this assumption does not prevent coexistence. Within each patch, competition is modeled by a difference form of the Lotka-Volterra equations.

The predictions of the aggregation model are that with k of the negative binomial < 1 (strong aggregation), it is virtually impossible for the competitively superior species to eliminate the competitively inferior species. **Figure 7** shows the model's results as a graph of "critical α " against k of the negative binomial. Critical α is the competition coefficient that the superior species must have in order to exclude the inferior species. Also shown on the graph are distributions of α and k for drosophilid flies. For these flies it is clear that k of the negative binomial is usually < 1 and that competition coefficients are not sufficiently large to prevent competitive exclusion. For many animals exploiting ephemeral and patchy resources, this model therefore provides a viable alternative to

Figure 7 Relationship between “critical α ” and aggregation (k of the negative binomial) predicted by the aggregation model.

traditional resource partitioning as an explanation for the coexistence of species. The two-species model has been extended to a many-species model (Shorrocks and Rosewell, 1987) and predicts average group sizes of about seven species coexisting on identical resources.

Laboratory Experiments

Yeast and Paramecium

In the early part of this century, G. F. Gause carried out a series of simple experiments with yeasts and protozoa that are instructive, are of historic interest, and set the experimental protocol for many of the so-called “bottle” experiments conducted in the 1940s, 1950s, and 1960s. His early experiments are detailed in his classic book *The Struggle for Existence* (Gause, 1934). He was mainly interested in testing the Lotka–Volterra model that had been put forward as a description of the competitive process, between species, a few years earlier.

The experimental design was simple. He grew two species, each alone and then together in mixed culture, to determine the course of competition under laboratory conditions. In his first experiments he used two species of yeast, which he called *Saccharomyces* and *Schizosaccharomyces*. However, we are not now sure of the exact taxonomic identity of the two species. He grew these species on an extract of brewer’s yeast, water, and sugar. The growth medium was not renewed, but growth ceased before the sugar resource was exhausted, apparently because of the accumulation of alcohol. These experiments with yeast are therefore an example of interference competition rather than exploitation competition. The main interest of these experiments lies in the calculation of the competition coefficients (α), which Gause did by estimating all the variables in the Lotka–Volterra competition equations except α . The intrinsic rate of natural increase (r_1 and r_2) and

the carrying capacity (K_1 and K_2) were estimated by fitting a logistic equation to the single-species growth curves. From the mixed cultures, he estimated both the numbers of each species (N_1 and N_2) and the growth rates (dN_1/dt and dN_2/dt). By rearranging the Lotka–Volterra equations he obtained

$$\alpha_{12} = \frac{K_1 - \frac{dN_1/dt \cdot K_1}{r_1 \cdot N_1} - N_1}{N_2}$$

$$\alpha_{21} = \frac{K_2 - \frac{dN_2/dt \cdot K_2}{r_2 \cdot N_2} - N_2}{N_1}$$

Since all quantities on the right-hand side are known, he could estimate the competition coefficients (α_{12} and α_{21}). Since N_1 , N_2 , dN_1/dt and dN_2/dt all vary with time, Gause selected three occasions during his experiments to estimate α . He then took the mean of these three calculations. His experiments were also repeated under two environmental conditions, which he called anaerobic (yeasts grown in test tubes) and aerobic (yeasts grown in flasks). Since α is a measure of the effect that one individual of species 1 has on the population growth of species 2 (and vice versa), and with these species competition is thought to be mainly the result of alcohol poisoning, it should be possible to calculate α directly from the relative production of alcohol by the two species. Table 2 shows the values of α calculated from population experiments and relative alcohol production, under both anaerobic and aerobic conditions.

Two important points come out of these yeast experiments. First, the competition coefficients are not constant; they vary (quite markedly) with different environmental conditions. Second, relative alcohol production and its effect on growth are sufficient to explain the interference competition between these two species (particularly under aerobic conditions).

Therefore, in this experiment, the competition coefficients are relatively simple, pure quantities and $\alpha_{12} \cong 1/\alpha_{21}$

In his later and perhaps more famous experiments, Gause used two species of single-celled protozoa called *Paramecium*. Initially he used what he called *P. caudatum* (1) and *P. aurelia* (2), although once again we are not sure about the precise taxonomy because these species are now known to be closely related groups of species. The *Paramecium* were grown in 5 cm³ of Osterhaut's medium (a mixture of salts) in test tubes at 26 °C. Each day fresh food was added to the test tubes. The food was a bacterium grown on agar plates and added to the cultures using a platinum loop (to standardize the amount given). The bacterium used did not grow in Osterhaut's medium. Each experiment was started with 20 *Paramecium* individuals on Day 0, and Gause estimated the number of individuals each day by sampling 10% of the medium. Since

Table 2 Competition coefficients (α) calculated from yeast population experiments and relative alcohol production, under both anaerobic and aerobic conditions

	Experiments	Alcohol
Anaerobic		
α_{12}	3.15	2.19
α_{21}	0.44	0.46
Aerobic		
α_{12}	1.25	1.25
α_{21}	0.85	0.80

an individual of *P. aurelia* occupies only 39% of the volume of a single *P. caudatum*, he estimated the volume of a typical cell for each species and converted the estimated numbers to biomass (in volume). Following the same protocol as the yeast experiments, the two species were grown alone (four cultures of *P. caudatum* and three cultures of *P. aurelia*) and in mixed culture (three cultures); **Figure 8** shows the mean volumes, over time, for these experiments. In single culture, both species appear to grow to an equilibrium at around $K=200$. In mixed culture, *P. caudatum* appears to suffer more from interspecific competition than does *P. aurelia*, although the latter also grows less well. Using the same procedure as for the yeast experiments, Gause was able to estimate the competition coefficients (α_{12} and α_{21}), and these are given in **Table 3**.

Notice that in the first few days the competition coefficient for the effect of *P. aurelia* on *P. caudatum* is negative. This implies that the effect of *P. aurelia* is actually positive at this stage. Given that $K_1=K_2=200$, $\alpha_{12}=1.64$, and $\alpha_{21}=0.61$, then we can calculate $K_1/\alpha_{12}=122$ and $K_2/\alpha_{21}=328$ and therefore construct the Lotka–Volterra phase-plane for this experiment.

Table 3 Competition coefficients calculated from Gause's *Paramecium* experiments

	α_{12}	α_{21}
First day	− 1.00	+ 0.50
Greater than fifth day	+ 1.64	+ 0.61

Figure 8 Growth in volume of *Paramecium caudatum* and *P. aurelia* in both single and mixed culture (from Gause, 1934). Volumes are converted from number of individuals per 0.5 cm³ in the culture. Since the volume of *P. caudatum* was set at 1.00 and that of *P. aurelia* at 0.39, the volume for *P. caudatum* is equal to the number of individuals per 0.5 cm³.

Figure 9 Phase-plane graph showing the experimental trajectory from **Figure 8**. Numbers are actually the “volume” of each species. Intercepts (and therefore zero isoclines) are worked out from Gause’s experimental data (see text). The predicted equilibrium is indicated by an asterisk.

This is shown in **Figure 9**, along with the two-species population trajectory for the results in **Figure 8**. These experiments with *Parametecium* appear to broadly confirm the predictions of the Lotka–Volterra model of interspecific competition, although the mortality imposed by the sampling procedure (10%) and the premature termination of the experiments result in the predicted equilibrium not being reached in 25 days. However, later experiments in which Osterhaut’s medium was buffered to a pH of 8 and the daily food concentration was reduced resulted in *P. caudatum* being excluded from the cultures in just 16 days.

In another set of experiments using *P. aurelia* and *P. bursaria*, Gause obtained population trajectories that suggested coexistence, although again the experiments were not run for long enough to reach an actual equilibrium. However, irrespective of the starting numbers, the two-species population trajectories converge on the same joint densities. *Parametecium bursaria* is interesting since it contains within its cell body unicellular green plants. The suggestion has been made that *P. bursaria* was able to exploit the bacterial food that had settled at the bottom of the experimental tube. This area of the microhabitat is depleted of oxygen (by the bacteria) and cannot be used by *P. aurelia*. However, *P. bursaria* carries its own oxygen supply (produced by its unicellular plants) and can use this part of the bacterial resource. Heterogeneity within this simple habitat, produced by the bacterial food, may have been sufficient to allow resource partitioning.

Table 4 Average densities of beetles observed in Park’s single species experiments

	34 °C	29 °C	24 °C
<i>T. confusum</i> (1)			
70%	41	33	29
30%	24	30	30
<i>T. confusum</i> (2)			
70%	30	50	45
30%	10	19	3

Table 5 Comparison of Park’s single-species beetle experiments

	34 °C	29 °C	24 °C
70%	1 > 2	2 > 1*	2 > 1*
30%	1 > 2*	1 > 2*	1 > 2*

Asterisks indicate that *T. confusum* and *T. castaneum* maintained significantly different population sizes.

Flour Beetles

In a series of studies, Thomas Park carried out competition experiments between two species of flour beetle, *Tribolium confusum* (1) and *T. castaneum* (2). Both are frequently found as stored-product pests and they can be conveniently raised under laboratory conditions. Populations were kept in glass tubes with 8 g of medium (95% flour and 5% yeast). All adults, pupae, and larvae were counted every 30 days and both single- and mixed-species populations were kept. An interesting aspect of the experimental design, which proved instructive, was that populations were maintained at a number of temperatures (24, 29, and 34 °C) and relative humidities (30% and 70%), and each type of population (single or mixed), under all six environmental conditions, was replicated 30 times.

Single-Species Results

Apart from *T. castaneum* at 24 °C and 30% humidity, all single-species populations persisted, and **Table 4** shows the average population densities during the course of the experiment. The value of 3, for *T. castaneum* at 24 °C and 30% humidity, is the average population density until extinction.

Using these average densities as an indication of success, Park compared the relative performance of these two species (alone) for each temperature/humidity combination. The results of this comparison are shown in **Table 5**, where an asterisk indicates a statistically significant difference between the two species. Except for 34 °C and 70% humidity, each of the physical environments significantly favors one species over another. These results are due to intraspecific competition and the effect of the physical environment on it.

Two-Species Results

Park found that while single-species populations persisted (with the exception of *T. castaneum* at 24 °C and 30% humidity), mixed-species populations did not. In each population only one species persisted and the other was eliminated. However, unlike most previous bottle experiments

(e.g., Gause's experiments), it was not always the same species that was eliminated, even under the same environmental conditions. This "indeterminate" outcome of competition is one of the predicted possible outcomes of the Lotka–Volterra model. Table 6 shows the percentage of replicates that *T. castaneum* won.

These experiments illustrate two interesting and possibly universal features of competition. First, the outcome of two-species competition can sometimes be predicted from the performance of each species on its own (i.e., 29 °C/70% and 24 °C/30%), but also *sometimes it cannot* (i.e., 34 °C/70% and 24 °C/70%). Second, the outcome of competition between two species can vary along an environmental gradient. Park's experiments go from hot–humid conditions (34 °C/70%) to cool–dry conditions (24 °C/30%). At the hot–humid end, *T. castaneum* eliminates *T. confusum* each time. At the cool–dry end, *T. confusum* eliminates *T. castaneum* each time. In the middle region either species can win, but *T. castaneum* wins more often toward the hot–humid end, and *T. confusum* wins more often toward the cool–dry end. If we imagine that the isoclines in the Lotka–Volterra phase-plane graphs can move their position depending on environmental conditions, then these *Tribolium* results are still understandable in terms of the Lotka–Volterra model. Figure 10 presents a series of phase-plane graphs, going from hot–humid (left) to cool–dry (right). The arrow(s) in each diagram indicate the equilibrium point. Notice that the species predicted to win moves from always *T. castaneum* (left), to either species, to always *T. confusum*.

Drosophila

In the late 1960s and early 1970s, Francisco Ayala conducted a series of laboratory experiments, each using a pair of *Drosophila* species. Although five species were used in different combinations, the basic design and outcome of all of these experiments were very similar. One experiment, between

D. serrata and *D. pseudoobscura*, will be sufficient to illustrate the apparent dilemma that emerged.

Drosophila serrata comes from Australia and *D. pseudoobscura* comes from North America. Notice therefore that since neither of these flies comes from the same continent, let alone the same community, Ayala was simply using the flies like analog computers to find out what might happen between flies in real communities.

At 25 °C, *D. serrata* eliminates *D. pseudoobscura* in a few generations; at 19 °C, *D. pseudoobscura* eliminates *D. serrata*. Ayala performed his experiments at 23.5 °C, at which temperature the two species coexisted. Populations were started with 300 adult flies of each species and were maintained in a series of milk bottles with standard *Drosophila* medium (a kind of yeasty porridge). Adult flies feed off the yeasty surface of the medium, female flies lay their eggs onto the surface, and larvae feed within it. Third instar larvae pupate on the surface of the medium or on the side of the bottle. When an apparent equilibrium was reached in the mixed populations, single-species populations were established and maintained under the same conditions. From the population data, and assuming that the Lotka–Volterra model of competition describes what is happening between the two species, Ayala was able to calculate the competition coefficients, α_{12} and α_{21} . He did this in the same manner as Gause, by rearranging the Lotka–Volterra equations:

$$\alpha_{12} = \frac{K_1 - \frac{dN_1/dt \cdot K_1}{r_1 \cdot N_1} - N_1}{N_2}$$

$$\alpha_{21} = \frac{K_2 - \frac{dN_2/dt \cdot K_2}{r_2 \cdot N_2} - N_2}{N_1}$$

However, by assuming that the two-species populations had reached an equilibrium ($dN_1/dt = dN_2/dt = 0$), these equations can be reduced to

$$\alpha_{12} = \frac{K_1 - N_1}{N_2}$$

$$\alpha_{21} = \frac{K_2 - N_2}{N_1}$$

where K_1 and K_2 equal the equilibrium population densities of each species on their own and N_1 and N_2 equal the

Table 6 The percentage of replicates that *T. castaneum* won in Park's beetle experiments

Figure 11 The nature of density dependence in Ayala's model.

equilibrium population densities for each species in the mixed populations.

All the pairs of species that Ayala studied coexisted for many generations, however, in every case he found that

$$\alpha_{12} > \frac{K_1}{K_2} \text{ and } \alpha_{21} > \frac{K_2}{K_1}$$

This is not the “case for coexistence” in the Lotka–Volterra model of competition. Intriguingly, Ayala did not conclude that the model was incorrect, but rather that the species could coexist even if they utilized the same resources.

Of course, the Lotka–Volterra model incorporates the logistic equation, which assumes (as a first approximation) that the relationship between rate of increase and density is a straight line (see [Figure 2](#)). However, Gilpin and Justice examined the relationship between birth/death and density in Ayala's experiments and found that for these *Drosophila* it was frequently a curve. It is not surprising therefore that an apparent conflict had occurred between theory and practice. This led [Gilpin and Ayala \(1973\)](#) to develop a new Lotka–Volterra model that incorporated such “nonlinear” relationships. Their new model of competition has four parameters, one more than the Lotka–Volterra model, and explains 95% of the variance in Ayala's experiments. For two species, the model can be written as

$$\begin{aligned} \frac{dN_1}{dt} &= r_1 N_1 \left[1 - \left(\frac{N_1}{K_1} \right)^{\theta_1} - \left(\frac{\alpha_{12} \cdot N_2}{K_1} \right) \right] \\ \frac{dN_2}{dt} &= r_2 N_2 \left[1 - \left(\frac{N_2}{K_2} \right)^{\theta_2} - \left(\frac{\alpha_{21} \cdot N_1}{K_2} \right) \right] \end{aligned}$$

The new parameter (θ) describes the nonlinear nature of density dependence. When $\theta = 1$, the new model is identical with the Lotka–Volterra model. [Figure 11](#) shows the nature of density dependence when $\theta \neq 1$, < 1 , and > 1 . These modified Lotka–Volterra equations give zero isoclines, on an N_1 -by- N_2 graph, that are curves rather than straight lines. This leads to the intriguing possibility that more than one equilibrium may exist for a pair of competing species ([Figure 12](#)).

Field Experiments

Barnacles

Barnacles compete for space in the intertidal zone of rocky shores. Because they are attached to the rock, they are ideal animals for experimental manipulation in the field. In the

Figure 12 Two equilibrium points resulting from curved zero growth lines derived from the Gilpin–Ayala model.

1950s, Joseph Connell conducted a classic set of removal experiments to test for competitive interactions between two species of barnacle, *Chthamalus stellatus* and *Balanus balanoides*. The experiments were carried out on the Isle of Cumbrae in the Firth of Clyde, Scotland.

These two species occupy two separate horizontal zones (with a small area of overlap), with *Chthamalus* (which is more resistant to desiccation) higher up the shore. *Chthamalus* larvae settle on the shore in September/October, whereas *Balanus* settle in April/May. Connell selected eight areas for study, on different parts of the shore, and used old glass lantern slides (10.7 cm × 8.2 cm) as quadrats on which he could mark the position of all individuals of both species of barnacle.

After the settlement of *Balanus* had stopped in early June, a census of the *Chthamalus* was made. Each quadrat was divided into two halves and from one randomly chosen half all the *Balanus* individuals were removed. Survival of the *Chthamalus* individuals in both halves of the quadrats was then monitored for 12 months. [Figure 13](#) shows three representative results from three of the quadrats. What is quite clear is that survival of *Chthamalus* is much better in those halves of the quadrats without *Balanus*. Direct observation showed that this was due to interference competition from *Balanus* individuals who smothered, undercut, or crushed *Chthamalus* individuals. Those *Chthamalus* individuals in the *Balanus* half of the quadrat that survived the competition were smaller than those that had not been subjected to this interspecific competition, illustrating that competition affects fecundity as well as survival.

Ants and Mice

Seeds play a major role in the ecology of desert regions and the seeds of annual plants are the primary food of several distantly related taxa of specialized granivores, such as rodents, birds, ants, and beetles. In particular, rodents and ants are very similar in their utilization of seed resources.

Figure 13 Survivorship curves for *Chihamalus stellatus*, with (solid line) and without (dashed line) *Balanus balanoides*.

Table 7 Numbers of ants and mice in the exclusion experiments of Brown and Davidson

	Rodents removed	Ants removed	Control	% Increase
Ant colonies	543	—	318	70.8
Rodent numbers	—	144	122	18.0

In the desert near Tucson, Arizona, experiments demonstrated that ants and rodents take most of the seeds, harvest the same size and species, and collect them from the same microhabitat. Brown and Davidson performed a set of exclusion experiments to demonstrate competition between these two taxa. They established replicated, circular plots (36 m in diameter) in relatively level, homogeneous desert scrub, approximately 60 km northwest of Tucson. Two plots were subjected to each of the following treatments. (1) Plots were fenced to exclude seed-eating rodents. Those rodents present were removed by trapping. (2) Granivorous ants were removed by repeated application of insecticide to individual colonies. (3) Both of the preceding treatments were done. (4) None of the treatments were done (control experiment).

Over a period of several months, the ants were censused five times (colonies counted) and the rodents were censused twelve times (trapping). **Table 7** shows the “numbers” of ants and rodents in the different treatments at the end of the experimental period. In the “control” experimental plots both ants and rodents showed a decrease in “numbers” compared to their single-taxon plots. Both groups showed a negative effect, which was interpreted as competition for seeds. This suggestion is strongly supported by the fact that on plots from which both ants and rodents were removed, there was a 5.5 times increase in density of seeds. However, there was no difference in seed density between plots with ants + rodents, ants only, and rodents only.

Anolis Lizards

Anolis lizards are an important component of island terrestrial communities in the eastern Caribbean. In these communities,

anoles substitute for the ground-feeding insectivorous bird guild and are major components of the animal biomass. Joan Roughgarden and her colleagues have demonstrated the presence of competition between two species, *Anolis gingivinus* and *Anolis watsi*. Both species are insectivorous, territorial as adults, and somewhat arboreal in habit.

On the island of St. Maarten, distributional evidence suggests that there is present-day competition. *Anolis watsi* occurs only in the central hills of St. Maarten, whereas *A. gingivinus* occurs throughout the island including the central hills. This observation is interesting because all the relatives of *A. watsi* on nearby islands occur throughout all elevations and habitats, including sea-level habitats. Two other observations are suggestive of a competitive interaction between these two species. *Anolis gingivinus* shows a lower abundance and shifts its perch position where it co-occurs with *A. watsi*, relative to when it occurs alone. However, these observational data are not conclusive evidence of competition.

Roughgarden and colleagues therefore carried out some manipulative field experiments on a small cay close to St. Maarten. This very small island was essentially a limestone platform (100 m × 400 m), 15 m above sea level, with several vegetation groves consisting of sea grape, Manchaneel, and perennial grasses. This cay had a resident population of *A. gingivinus*, but lacked any *A. watsi*. **Table 8** shows the results

Figure 14 Foraging positions of five species of warbler in the coniferous forests of the northeastern United States. Shaded zones represent 50% of recorded time.

of four experiments carried out over a three-year period in three of the vegetation groves. In the experiments in grove SK (1979) and LU, marked individuals of *A. watsi* were released and the resident *A. gingivinus* were left undisturbed. Survival of *A. watsi* was low; most of the introduced individuals disappeared and those that were left did not establish territories in the center of the grove, only at the periphery. In the experiments in grove SK (1981) and MK, between 40% and 50% of the resident *A. gingivinus* were removed prior to introducing *A. watsi*. In these experiments, survival was twice that in the other experiments and some surviving *A. watsi* did establish territories in the center of the grove. It seems likely therefore that the restricted distribution of *A. watsi* (to the central hills) observed on St. Maarten is due to competitive exclusion of *A. watsi* by *A. gingivinus*.

Field Observations

New England Warblers

Many field studies of competition actually look for resource partitioning (niche separation) that would reduce interspecific competition, relative to intraspecific competition, and

therefore promote coexistence. Furthermore, these field studies frequently do not examine directly the resources used (types of seed or types of insect) but instead use surrogate measurements (bill size or foraging area). An example of this type of study is Robert MacArthur's work on New England warblers.

Five species of warbler (myrtle, black-throated green, blackburnian, bay-breasted, and Cape May) inhabit the spruce forests of Maine and Vermont in the US. All of these species nest in the forests of New England and winter in the Caribbean. The spruce forests in which they live and breed are uniform, without obvious variety. Their beaks are all the same size and shape and their stomach contents are approximately the same. In his study, MacArthur recorded how long each species spent foraging in each part of a tree. A tree was divided into 10-ft zones vertically and branches were divided into three horizontal zones: (1) the bare or lichen-covered base, near the trunk, (2) the middle zone of needles, and (3) the terminal zone of new needles or buds. He produced diagrams of trees showing the zones of foraging activity for each species of warbler (Figure 14). The resulting foraging distributions suggested a rather subtle kind of resource partitioning (assuming that foraging in different parts of the tree gives access to different sections of the insect resource being used by these birds).

Figure 15 Checkerboard distribution of *Pachycephala* flycatcher species on the Bismarck Islands off Papua New Guinea. *P* = *P. pectoralis*, *D* = *P. melanura dahlia*, and *O* = neither.

In addition to these zone differences, MacArthur also suggested differences in foraging behavior between the five species: “subjectively, the black-throated green appeared nervous, the bay-breasted slow and deliberate.” He quantified this by recording the length of time between “use of wings” and was able to show that the black-throated green had a shorter time interval than either the blackburnian or myrtle, which in turn had a shorter time interval than the Cape May and bay-breasted. He also recorded the direction in which each species predominantly moved while foraging. This could be vertical (up and down the tree), tangential (around the tree), or radial (from the center of the tree outward and vice versa). Again he found differences between the species.

MacArthur’s work suggests that even when two species overlap in foraging space, they examine that space differently, and therefore use a different part of the available resource. The five warbler species are clearly searching for their insect resources in different spaces and in different ways, but whether this is sufficient to promote coexistence between potential competitors is difficult to tell. In fact, we have no direct evidence that these warblers are even competing for limited resources.

Pacific Island Birds

A number of field studies have used patterns in spatial distribution as evidence of the effects of competition on species co-occurrence. This type of field observation is illustrated by Jared Diamond’s study (1975) of land-breeding birds on the Bismarck Islands off the coast of Papua New Guinea. Several pairs of ecologically similar species (good candidates for potentially strong competitors) showed what Diamond called

Figure 16 Incidence function for the cuckoo-dove *Macropygia mackinlayi* on the Bismarck Islands.

checkerboard distributions, for example, the two flycatchers *Pachycephala pectoralis* and *P. melanura dahlia* (Figure 15). These two species have mutually exclusive but interdigitating distributions, with only one of the two flycatchers present on any one island (some islands have neither species). These checkerboard distributions are consistent with the idea that two ecologically similar species are excluding each other from islands because of strong competitive interactions.

Although Diamond did not find many examples of checkerboard distributions among his island birds, he did find other evidence of a more diffuse type of competition by plotting what he called incidence functions. These are graphs in which the probability of occurrence on an island ($J = (\# \text{ of islands with the species present}) / (\text{total } \# \text{ of islands})$) is plotted against the number of species (S) on that island. Because of the species–area effect, S is also a measure of island size. Figure 16 shows the incidence function for the cuckoo-dove

Table 9 Population estimates for the spotted hyena population of the Serengeti

Macropygia mackinlayi. This is an example of a species that Diamond calls a “supertramp.” These species are excellent colonizers but are poor at persisting in the diverse communities of large islands. This absence of supertramps from large islands implies strongly that competition is important in structuring these island bird communities.

African Wild Dogs and Hyenas

Many field observations of “competition” have relied heavily on changing species numbers over time. For example, one species arrives in an area (or a resident species increases its numbers), while another species declines in abundance. An early case was that of two species of crayfish in Russian streams, first commented upon by Gause in his book that reported his early *Paramecium* experiments (Gause, 1934). Another well-cited example is the invasion and spread of the American gray squirrel (*S. carolinensis*) in Great Britain, followed by the decline and contraction of the native red squirrel (*Sciurus vulgaris*). Yet another example is provided by the increase in abundance of the spotted hyena (*Crocuta crocuta*) in the Serengeti-Mara ecosystem of Kenya and Tanzania and the subsequent decline of the African wild dog (*Lycaon pictus*).

Spotted hyenas are the most abundant large predator in the Serengeti-Mara savanna ecosystem. Between 1969 and 1976, the hyena population increased by 50%, probably as a response to the herbivore increase following the elimination of the rinderpest virus. Some estimates for the subsequent population of hyenas in the Serengeti are shown in Table 9. Over this period the wild dog showed a decline in numbers, with all remaining dog packs finally disappearing from the Serengeti in the early 1990s (Figure 17). During the early 1970s, part of this decline in wild dog numbers was certainly due to hunting, as wild dogs were regarded as vicious vermin to be exterminated. However, the reason for the later decline is less certain, but competition with hyenas may have been important.

Both of these predators hunt in packs and run down their prey (mainly Thomson's gazelle, wildebeest, and zebra). Hyenas frequently follow dog packs when they go hunting from a den (during the breeding season) and steal their kill. Dogs can defend a kill, but about four dogs are required to keep off one hyena. Although food on the “hoof” is probably not a limiting resource for large carnivores in the Serengeti, food in the form of “kills” may be. Particularly during the breeding season, dog packs are hunting not only for themselves but also for the dominant bitch and her pups back at

**Figure 17** Number of wild dogs in the Serengeti ecosystem.**Figure 18** Correlation between the population densities of wild dogs and hyenas over a number of African ecosystems.

the den. Losing kills to competitors such as hyenas may have a serious effect on pup survival. Because the ability of wild dogs to defend kills depends on the ratio of dogs to hyena, this effect may have become gradually more serious over the past 30 years. Additional evidence supporting this story comes from the correlation ($r = -0.92$, $P = 0.01$) between hyena density and dog density over a series of ecosystems in eastern and southern Africa (Figure 18).

Conclusions

The Lotka-Volterra model can theoretically predict the outcome of interspecific competition between two species. Depending on initial population size (N_1 and N_2), carrying capacity (K_1 and K_2), and competition coefficient (α_{12} and α_{21}), either species can be the sole survivor, one species is always the sole survivor (competitive exclusion), or the two species will coexist. What is more, coexistence is assured if $\alpha_{12}/K_1 > 1/K_2$ and $\alpha_{21}/K_2 > 1/K_1$, which implies that intraspecific competition must be greater than interspecific competition for both species. These predicted outcomes are local outcomes (within a habitat patch such as a fungal fruiting body, a freshwater pool, a coniferous wood, or an island

depending on the scale of the environmental grain appropriate to the ecology of the organism). Both the aggregation model of competition and resource partitioning predict “local” competitive exclusion, with global coexistence using different local mechanisms that ultimately have the same effect on competitive interactions.

There is considerable evidence, from laboratory experiments, that these models could describe what happens to some real organisms. Graphs of N_1 against N_2 (using K and α) predict the correct competitive outcome for *Paramecium aurelia* and *P. caudatum*, while a small amount of environmental heterogeneity allows sufficient resource partitioning for *P. bursaria* to coexist with *P. aurelia*. The *Tribolium* experiments show that initial numbers can influence which species will win the competitive battle, and these same experiments, plus those with *Drosophila*, show that more complex relationships can still be incorporated into the same theoretical framework.

Lastly, there is some evidence, from field experiments and field observations, that these mechanisms might operate outside the computer and laboratory. We see patterns of replacement reminiscent of competitive exclusion (Bismarck birds and Serengeti carnivores) and niche differences consistent with resource partitioning (New England warblers). We also see numerical changes, after removal or introduction, that are consistent with competitive effects of one species on another (desert ants and mice, Scottish barnacles, and Caribbean lizards). However, the field data tend to fit the patterns

predicted by theory rather than providing detailed parameter values for the models. Nonetheless, the ideas encapsulated within theoretical models, such as the Lotka–Volterra model, provide a believable framework within which to interpret complex species interactions in the real world.

Glossary

Altruism Assistance provided by an agent to other individuals at the expense of its own lifetime reproductive fitness.

Ethology The study of the behavior and social relations of animals.

Genetic terms A locus is a particular place on a chromosome (strictly speaking, an “address” on a chromosomal map) where a gene resides. This gene may be any one of several alternative types or alleles. A diploid cell contains two copies of each autosomal chromosome, and therefore, two genes at each autosomal locus – one from its mother and one from its father. A diploid cell in the “heterogametic sex” also contains two sex chromosomes, which may differ in form (one X, one Y), whereas in the “homogametic sex” it would have two X chromosomes. A haploid organism contains one gene at each locus. A genome is the set of all of an organism’s genes.

Inclusive fitness An individual’s inclusive fitness is its lifetime reproductive output if not assisted by others, plus the added reproduction it confers on each relative it helps, times the proportion r of genes identical by recent descent it

shares with that relative (Hamilton, 1964). In an outbred population of diploids with weak selection, $r = 1/2$ between full siblings, and between parent and offspring, $1/4$ between half siblings, between an individual and its grandchild, or between aunt and nephew, etc. Inclusive fitness thus defined represents the common interest of the autosomal genome, and is what natural selection maximizes (Grafen, 2006).

Mutualism A mutually beneficial association or interaction, temporary or permanent, among organisms of different species.

Parasitism An association among members of different species in which members of one species (the parasite) feeds on parts of the other’s (the host’s) body, or on resources the host has obtained. The parasite usually lives inside or on the host.

Social cooperation A mutually beneficial association, temporary or permanent, among members of the same species.

Symbiosis A mutualism among members of different species in which members of one species (the symbiont) live inside or on a body of the other (the host).

What are the Benefits and Dangers of Cooperation?

Natural selection is a competitive process. The winners are those genes which reproduce most successfully, and the individuals that carry them (Fisher, 1930; Hamilton, 1964). As competition in human economies causes people to cooperate so as to compete better with third parties, so in nature competition often favors the evolution of social cooperation among members of the same species, and mutualism, cooperation among members of different species, to compete better with others. Cooperative endeavor is essential to the productivity and diversity of ways of life in natural ecosystems, as it is to human economies.

The evolution of close cooperation among members of the same species was crucial to several major transitions of evolution, such as the evolution of sexual reproduction, multicellular plants and animals, and insect societies. Yet cooperation only evolves if cheaters, which appropriate the benefits of others’ cooperation without contributing, can be suppressed or limited. Many animals live in social groups with other members of their species because they depend in some way on each other’s activities. Yet an animal’s fellow group members are often its closest competitors – for food, mates, or living space. Life in social groups thus poses three questions: Why live in groups (Maynard Smith and Szathmáry, 1995)? What ecological circumstances, and what social mechanisms, prevent competition among group members from destroying their common interest in cooperating (Moynihan, 1998)?

How could such social mechanisms evolve (Leigh and Rowell, 1995)? Indeed, how social cooperation evolves is a central problem of ethology.

This problem of ethology has various analogs. First, human beings benefit from, and indeed depend on, social life. Nevertheless, individuals often appropriate for their private advantage an undue share of the common wealth created by social activity. From the time of Aristotle onward, philosophers and statesmen have struggled to learn how to organize a society so that individual advantage coincides most nearly with the common good.

Second, metazoans are complex multicellular animals. A metazoan’s cells usually serve their organism well. However, cancer suggests that conflict between an individual and one of its cell lines is a real, often devastating, possibility (Buss, 1987). How did the harmony among a metazoan’s cells evolve? How are conflicts between metazoans and their cells reduced or suppressed?

Mutualism between members of very different species evolves more easily. By definition, members of different species do not compete for mates. Because they have different needs, they compete far less intensely for food or shelter than members of a social group, and they are more likely to have different abilities that can be pooled for mutual benefit. Nonetheless, mutualism, like social cooperation, only evolves if cheating can be controlled or suppressed. Mutualism may involve encounters as brief as the dispersal of fig seeds by a bat that ate the fig containing them, and symbioses as prolonged

as that between an aphid and the bacteria in its gut that synthesize vitamins the aphid cannot live without (Leigh, 2010b; Douglas, 2010).

First, mutualistic partnerships can give rise to true individuals – a major transition in evolution. Eukaryotic cells, whose chromosomes are separated from the cytoplasm by a nuclear membrane, provide the clearest example of this process. Most eukaryotic cells contain organelles, mitochondria and chloroplasts, with genomes of their own that reveal their ancient ancestors – bacteria that invaded ancestors of their host cells about two billion years ago (Margulis, 1993). Nowadays, organelles are essential to their host cells. Cells require mitochondria to obtain energy by oxidizing carbohydrates to release carbon dioxide and water. Leaves cannot photosynthesize unless their cells contain chloroplasts. Despite organelles' crucial importance to their host cells, conflicts between them can arise. Fertilized eggs that receive organelles from both parents may be ruined by the struggle for dominance between maternally and paternally derived organelles. Organelles might multiply faster at the expense of serving their host (Eberhard, 1980). How are these conflicts resolved effectively enough to make a coherent individual out of a cell and its organelles?

Second, genes are the “ultimate” units whose selfinterest drives evolution in the sense that no characteristic evolves nonrandomly unless it serves the selfinterest of some gene (Dawkins, 1982). However, an individual gene, divorced from the rest of its genome and an organism appropriate for the genome's expression, is as useless as a piece of computer program without the rest of the program, a computer that can run the program, and an operator who can run the program on that computer. Thus, these ultimate units of selfinterest are utterly dependent on each other. Chromosomes express the mutual advantage that different kinds of genes derive from each other's presence – their mutual dependence on each other's functions. In particular, chromosomes maintain their genes' continued association by ensuring their simultaneous replication (Maynard Smith and Szathmáry, 1995). Indeed, a genome's genes can be thought of as one of the closest and most intimate of all mutualisms. However, some types of genes, which do nothing to benefit the organisms that carry them, multiply independently of the chromosomes, threatening to fill their genome with selfish DNA. How is this sort of destructive competition prevented from draining away the common wealth of the genome?

Third, conflicts can also occur between chromosomal genes and their genome. Meiosis, the process whereby a gamete is assigned one gene at each locus, is usually as fair a lottery as nature can devise, in the sense that at each locus a gamete has equal chance of inheriting its grandmother's or grandfather's gene. When meiosis is fair, that is say, when a gamete has equal chance of inheriting either allele at a heterozygous locus, natural selection favors an allele only if it enhances the survival or reproduction of the organisms carrying it: thus fair meiosis reflects the common interest of an individual's autosomal genes, its autosomal genome. However, a few alleles that injure their bearers spread by biasing meiosis of heterozygotes in their own favor. Such alleles are called segregation distorters. Some experimental populations have been wiped out by the spread of such alleles (Leigh and Rowell, 1995).

Why is meiosis normally so fair when segregation distortion can spread alleles so effectively?

Finally, like human economies, ecosystems are both arenas of competition and webs of mutualistic interdependence (Leigh, 1999). Are ecosystems the greatest of all mutualisms? Human influence on natural ecosystems, especially unintended influence, is usually damaging: ecologists call such influence “disturbance.” In accord with this language, natural ecosystems are organized for high productivity and diversity, in the sense that unprecedented “random” disturbance depresses one or the other, just as Aristotle, like Fisher (1930), argued that organisms are organized, adapted to survive, and reproduce because visibly mutant individuals usually do so less well than their normal counterparts. Despite the abundance of natural enemies (predators, parasites, and pathogens), organisms depend on their ecosystems for the necessities of life, even the air they breathe. Therefore, organisms share a common interest in their ecosystem's integrity, as if ecosystems are true “commonwealths.” Does the common interest of organisms in the integrity of their ecosystem influence the evolution of individual species? If so, how? These are among the greatest mysteries of biology (Leigh, 1999).

The Evolution and Maintenance of Cooperation

Cooperation evolves only if the potential partners all benefit from it. In other words, there must be advantages which are most easily or effectively obtained by cooperating, and all partners must benefit from cooperating, even if unequally. In sum, cooperating must truly serve a common good.

What can be Gained by Cooperating?

Among members of the same species, the most basic form of cooperation is sexual reproduction, by which two individuals jointly produce offspring of more varied genotype than those that either could produce alone (Maynard Smith and Szathmáry, 1995). Sexual reproduction and the associated exchange of homologous chromosomes, creates the selection that maintains the fairness of meiosis. In turn, fair meiosis ensures that alleles spread only if they benefit their bearers (Leigh, 2010a). Sexual reproduction also allows an allele to be tested in a variety of genotypes, so that its spread is governed by its own contribution to fitness rather than the merit of the genotype in which it first happened to appear (Fisher, 1930; Felsenstein, 1974). Thus, other things being equal, selection favors alleles that are good mixers which benefit all the genotypes that include them, which in turn favors a modular expression of gene action. In other words, sexual reproduction favors genetic systems organized to facilitate adaptive evolution (Fisher, 1930). In many species, cooperation for sexual reproduction is prolonged. For example, among insectivorous birds and some fish, the parents share the labor of, or divide the tasks involved in, feeding, sheltering, and defending the young.

Members of a species join in larger groups, as a rule, if grouping enhances safety or effectiveness (Moynihan, 1998).

They may combine for greater safety against predators because, with more eyes, predators are detected sooner or because members of a group can coordinate activities to confuse or repel predators. A group may also be able to overcome a competitor, or a large prey animal, which could defeat any one of its members. Finally, the advantages of a suitable division of labor drove the evolution of insect societies, some of which attained enormous size and great complexity.

Mutualisms among members of different species usually involve complementation of different functions (Leigh, 2010b). Thus, a coral provides its symbiotic algae with nutrients from small animals that the coral polyps catch. In return, the coral receives carbohydrates from the photosynthesis of these algae. A plant provides its pollinators with nectar or pollen in hopes that these mobile animals will convey some of this pollen to another plant of the same species. Some plants provide food and shelter for specific kinds of ants, which repel most of their host plant's herbivores and destroy the growing tips of vines that would otherwise overgrow their host plant.

What Keeps Cooperation from Becoming Parasitism?

Cooperation involves the pooling of labor to create a common good. Why don't some members of a social group cheat their partners rather than collaborating with them? What keeps an individual from exploiting a good created by a partner in mutualism without offering any benefits in return?

Social Cooperation and Kin Selection

An individual's alleles can spread if the individual helps close relatives reproduce at little cost to itself: this is called kin selection (Hamilton, 1964). A child inherits half its mother's genes, one of the two genes at each of its mother's loci. Thus, alleles of either mother or child can spread if their carrier helps the other relative reproduce. Indeed, kin selection expresses the common interest of an individual's autosomal genes.

Kin selection plays a crucial role in the evolution and maintenance of insect societies. A wasp lays an egg where the hatching larva has immediate access to food. Often, this is a provisioned nest cell. Sometimes, solitary nesting is futile because unguarded nests are always robbed of their eggs or provisions. Communal nesting makes for better-defended nests but intensifies competition for nest cells and provisions, creating winners and losers. If winners and losers are related, it may be more profitable (as measured by the numbers of copies of the loser's alleles propagated to offspring) for the loser to help the winner reproduce, perhaps by provisioning the winner's nest while the winner guards it. Relatedness to the winner enables the loser to benefit from cooperating with it, but their common interest in a defended nest is equally essential to their cooperation.

In most insect societies with division of labor, a single queen usually produces all the young (Fisher, 1930), and most of her daughters are workers who help the queen reproduce. All such societies descend from societies where a queen mates with a single male, ensuring that workers are closely related to each other as well as the queen (Leigh, 2010a). In very large,

crowded, colonies, however, the queen mates with many males and mixes the sperm thoroughly to create the genetic diversity among workers needed to resist disease. At least in honeybees, this genetic diversity is also needed to ensure an adaptive distribution of workers over tasks (Mattila and Seeley, 2007). Workers share a common interest in helping their queen if it is impossible, or at least much less effective, for them to reproduce on their own. Among ants, workers are either sterile or lay eggs so slowly that they do better to help their queen (Hölldobler and Wilson, 1990). Because a honeybee queen mates with many males, most of a worker's colleagues are half-sisters. Because a worker is more closely related to her mother's egg than to a half-sister's egg, workers eat eggs laid by half-sisters, rendering worker reproduction futile (Seeley, 1995). The queen thereby creates selection favoring mutual policing among workers to enforce their common interest in helping their queen. This community of interest among the workers makes beehives models of self-organization, where workers perform their tasks, change from task to task, and adjust appropriately to changed circumstances automatically without the queen exerting direct control (Seeley, 1995). Kin selection is crucial to the evolution of these insect societies, but other arrangements are needed to create a strong enough community of interest among the workers for truly complex insect societies to evolve.

Selection among Groups

Selection among groups is one type of kin selection. Suppose that each individual mates only with fellow members of its group, no migrants are exchanged among groups, and each group is founded by emigrants from a single parent group. Then the groups are endogamous. This endogamy, or inbreeding, eventually makes a group's members so nearly genetically uniform, so much more closely related to each other than to outsiders, that an individual's reproductive advantage coincides almost precisely with its group's good as measured by its reproductive success (Leigh, 2010a). In other words, the raw material for natural selection is genetic variation. If genetic variation among a group's members exceeds variation among groups (variance among group means), selection among individuals within a group usually overrides selection among groups. Only if endogamy is so strong that variation among groups exceeds variation within groups can selection among groups prevail. In the 1950s, selection among groups was often invoked to explain cooperation. In 1966, however, George Williams showed that very stringent conditions were required for the good of the group to override individual advantage, and interest in selection among groups diminished greatly (Leigh, 2010a). Nevertheless, selection among groups sometimes enforces cooperation.

To understand how endogamy increases relatedness among a group's members, try the following experiment. Set 10 pennies on a table, five with heads up and five with tails up. Every minute, choose two pennies at random, one to "die" and the other to "reproduce." This is symbolized by turning over the first penny, if need be, so that it has the same side up as the second. In a short period of time, all pennies will have the same side up. If one uses more pennies, still starting with half heads and half tails, uniformity takes longer to achieve but eventually prevails. Next, represent migration

from outside by choosing a penny at random every 5 or 10 min and tossing it to see which side should be up. Now, uniformity is achieved more rarely and briefly, if ever.

How endogamous must groups be to allow selection among groups to work? Let groups, as well as individuals, have finite lifetimes. The intensity of selection among groups on a characteristic is the proportionate increase in the number of groups founded per preexisting group per group lifetime conferred by its members' possession of this characteristic, just as the intensity of selection among individuals on this characteristic is the proportionate increase that this characteristic confers on an individual's lifetime reproductive success, relative to fellow group members. Selection among individuals balances an equally intense selection among groups on the same characteristic if (1) each group descends from a single parent group, and one migrant is exchanged per two groups per group lifetime, or (2) no migrants are exchanged but one of every N groups is founded by the joining of colonists from two parent groups, where N is the number of mature individuals per group (Leigh, 2010a). Moreover, selection among groups is unlikely to override strong within-group selection unless there are many more groups than individuals per group. In sum, selection among groups is decisive only if groups are definite individuals in their own right.

Selection among groups played an integral role in the evolution of metazoans. All metazoans descend from sexually reproducing ancestors, whose young began life as a fertilized egg or zygote. A zygote grows by dividing mitotically so that an animal's cells all have the same genotype. Each individual is therefore genetically unique, but (mutations excepted) an individual's cells are genetically identical. Moreover, selection favors cells that can distinguish "self" from "nonself," thereby preventing the exchange of migrant cells among individuals. These circumstances identify the reproductive interests of an animal very closely with those of each of its cells (Maynard Smith and Szathmáry, 1995).

Mutants do occur, however, and cancerous cell lineages can run riot at their organism's expense. Multicellular plants and animals have many features which enhance the harmony among an individual's cells (Buss, 1987). In some groups of animals, the "germline" is sequestered, preventing a cancerous lineage from spreading to an individual's offspring. This circumstance is analogous to a honeybee or ant queen preventing worker reproduction to create a common interest among them in helping her reproduce. In some species, the mother's genes control the early stages of the development of her young just as, by judicious distribution of food or hormones, the queen of a complex ant society apportions her workers among different "castes," thereby programming a suitable division of labor for her colony (Hölldobler and Wilson, 1990).

Vertically Transmitted Partners in Mutualism and Group Selection

Intimate mutualisms, where members of one species, the symbionts, live inside members of the other, larger species, the host, are called symbioses (Douglas, 2010). Cooperation within symbioses is maintained if each host's symbionts can only be transmitted to its offspring (vertical transmission). Vertical transmission creates a selection among groups of

symbionts for benefitting their hosts, each group consisting of one host's symbionts.

Selection among groups played a crucial role in evolving mutualism between organelles and their host cells. Cells do not exchange organelles. Each cell receives its organelles from a single preexisting cell. This is usually, but not quite always, true even of zygotes. Most kinds of eukaryotic organisms have evolved means to ensure transmission of organelles from one parent, usually the mother. Organelles are therefore subject to a stringent selection among groups (each group being the organelles of given type in one cell) in their host's interest: indeed, organellar reproduction depends utterly on the reproductive success of their hosts (Leigh, 2010b).

How did organelles become susceptible to selection among their hosts? Consider mitochondria. The mitochondrial ancestors which first invaded host cells were parasites (Davidov and Jurkevitch, 2009). In some parasites, selection favors increased dispersal from one host to another, although this injures their current host's welfare. For others, selection favors caring for their current host even if this reduces the effectiveness of dispersal. It depends on how greatly increasing dispersal impairs the current host's usefulness, which differs from case to case. The complementation of functions between a host cell which procures food and an ancestral mitochondrion with aerobic respiration which metabolizes food far more effectively than the host can, presumably favored symbionts which cared for their current hosts. As a house cat defends its owner's house against conspecifics, so ancestral mitochondria defended their valuable hosts against conspecific invaders. Thus, migration of mitochondria between cells was prevented, thereby subjecting the mitochondria to selection among host cells. Selection among hosts favored mechanisms ensuring uniparental transmission of organelles when their hosts reproduced sexually, thereby perfecting the mechanism maintaining mutualism between host cells and their organelles (Leigh, 2010a).

Vertical transmission of symbionts and exclusion of immigrants from other hosts preserve a wide range of mutualisms. For example, aphids depend on bacteria in their guts to synthesize vitamins the aphids need: in turn, the bacteria depend on their hosts for carbohydrates and shelter: mothers pass on these bacteria to their offspring (Douglas, 2010). Similarly, leaf-cutter ants farm a fungus which the ants nourish with leaf fragments they cut from nearby trees. The ants eat certain parts of the fungus they cultivate, and also feed these fragments to their brood. Mutualism between ant and fungus is preserved because the fungus reproduces only when a new leaf-cutter queen takes a mouthful of fungus from its mother's nest to start a fungal culture in her own. Leafcutters carefully remove foreign fungal spores, preventing both infection by pathogenic fungi and immigration of symbiotic fungi from other nests (Hölldobler and Wilson, 1990).

Choosing Cooperative Partners

How can symbioses be maintained when hosts must call their symbionts from their surroundings rather than inherit them from these hosts' mothers? One approach to the problem is to test the usefulness of potential symbionts, and choose only those that pass the test, as a female bowerbird judges the versatility and stamina of her suitors by the size and

attractiveness of the bowers they build (Leigh, 2010b). Nocturnally active bobtail squid, *Euprymnia scolopoides*, are past masters at choosing functional partners. These squid depend on symbiotic bioluminescent bacteria, *Vibrio fischeri*, to adjust their shade to match that of the surrounding seawater, in effect hiding the squid from both its prey and its predators. In return, the squid houses its bacteria and feeds them abundantly. Margaret McFall-Ngai and Edward Ruby have documented how these squid choose appropriate symbionts (Leigh, 2010b). When only two hours old, a hatchling squid calls gram-negative bacteria from the surrounding water, trapping those responding to the call in mucus. Many are called, but few are chosen. After a few hours, only *Vibrio fischeri* remain from all the bacteria that responded to the call. These *Vibrio* then enter ducts leading from the squid's undersurface to its light organs. To reach and colonize these organs, however, these *Vibrio* must run an obstacle course quite as rigorous as any a fairy-tale swain must surmount to win his princess. The *Vibrio* must be able to move, survive strong acidity and potent microbicides, release compounds that make the squid's light-organs a suitable home for them, and produce light, before they can multiply and fill their new home (Leigh, 2010b).

Partner Fidelity and Entangled Fates

Some partners in mutualism are so dependent on each other that injuring one imperils the other. For example, if two men, each capable of wielding only one oar, are in a stormy sea, both must row if either is to reach shore and survive (Maynard Smith and Szathmáry, 1995). Their fates are conjoined: failure of one to cooperate kills both. Similarly, in monkey species such as *Cebus capucinus*, which live in groups that fight each other to maintain territories large enough to supply sufficient food even in the season of shortage, injuring a fellow group member injures the group's capacity to fight. If emigration to other groups is difficult or impossible, a group's monkeys share a common interest in their group's welfare that promotes cooperation (Leigh and Rowell, 1995).

J.L. Wulff (2008) has documented mutualism among three species of branching coral reef sponges. Sponges of each species grow better and live longer if intertwined with a sponge of one of the other two mutualistic species than if it grows alone, or intertwined with another of its own species. This mutualism arises because each partner contributes the ability to resist different hazards to the pair's mutual benefit: each species resists different diseases, different predators, and different abiotic threats such as sedimentation or breakage by storms. When a predator or disease attacks a sponge of a vulnerable species intertwined with one of a resistant species, at least those parts of the vulnerable species attached to the resistant one survive to grow again another day (Wulff, 2008).

Enforcement by Hosts of Cooperation from Live-in Symbionts

In many symbioses, hosts must supply food to their symbionts to enable them to provide benefits in return. The symbionts, however, must often expend copious energy to cooperate in the desired manner. In such symbioses, hosts of many species enforce cooperation by denying uncooperative symbionts resources they need to survive and reproduce (Leigh, 2010b).

In plants of the family Leguminosae, roots release chemicals that attract nitrogen-fixing bacteria, which use carbohydrates supplied by their hosts to convert atmospheric nitrogen, N_2 , into ammonia. When the exchange of signals between bacteria and host root is appropriate, the plant lodges these bacteria, called rhizobia, in nodules in their roots, where they are supplied with oxygen and the carbohydrate fuel they need to live, reproduce, and turn atmospheric nitrogen into ammonia. Chemical signals can lie, however: unlike bobtail squid, these plants cannot assess the cooperativeness of their bacteria before lodging them. If, however, a nodule's bacteria do not produce ammonia, the plant host cuts off the nodule's oxygen supply, halving these bacteria's fitness (Kiers and Denison, 2008). Similarly, many corals attract symbiotic algae, zooxanthellae, from the surrounding water, lodging them in their polyps, where the algae supply their host corals with carbohydrates in return for a safe place to live and the nutrients released when their host polyp digests organisms that it has snared. If, however, zooxanthellae cease to produce carbohydrates, their host coral expels them (Leigh, 2010b).

Mutual Enforcement

Mutual enforcement is vital to maintaining many cooperative endeavors, within both social groups and mutualistic partnerships. The author mentioned previously how honeybee workers mutually enforce their common interest in helping their queen reproduce. By eating each other's eggs, they make it pointless for workers to lay eggs on their own rather than helping their queen.

An analogous mechanism enforces the fairness of meiosis. Fair meiosis ensures that selection favors only those alleles that benefit their carriers. Some "distorter alleles," however, bias meiosis in their own favor (Leigh, 2010a). Up to 95% of the sperm of an individual heterozygous for a segregation distorter carry the distorter allele. If individuals homozygous for the distorter die childless, the distorter allele spreads until death of its homozygotes balances its spread from biased meiosis. Imagine a mutant at a locus on another chromosome whose only effect is to restore fair meiosis in all its bearers. Because alleles on different chromosomes assort independently at meiosis, no allele at this mutant's locus can benefit from the distorter's bias. This mutant spreads because it prevents the distorter's spread among its bearers and thus spares some of its bearers from death caused by being homozygous for the distorter. Because mutants which restore fair meiosis are favored at loci on every chromosome but the distorter's, fair meiosis expresses the common interest of the genome as a whole. This selection, which depends on sexual reproduction and recombination of genes on homologous chromosomes, has been demonstrated empirically. Therefore, even though genes are the ultimate units of selfinterest which drive evolution, it is reasonable to analyze the adaptation of whole animals.

The most familiar form of mutual enforcement is reciprocal altruism – help those who help you, and make it stick by retaliating against those who cheat you (de Waal, 1996). Reciprocal altruism is illustrated by the sexual behavior of hamlets, simultaneously hermaphroditic coral reef fish, studied by Eric Fischer (Leigh and Rowell, 1995). Even though a sperm is much smaller and "cheaper" than an egg, a successful

sperm contributes as many genes to future generations as a successful egg. Thus the common interest of autosomal genes favors hermaphrodites that devote as much energy to male functions – making great quantities of sperm, fighting or otherwise competing with each other for mates, and so on – as to the female functions of bearing and raising young. The proportion of a population's reproductive effort devoted to male functions represents the "50% cost of sexual reproduction." Hamlets avoid this cost by pairing off at mating time and alternating sex roles in successive spawns (matings). The fish which releases eggs during one spawn fertilizes the other's eggs during the next. This "egg-trading" short-circuits competition for mates and permits much lower sperm production, greatly reducing the cost of male functions. Reciprocation is favored even though it is cheaper to play the male role. At successive rounds of reciprocal spawns, each partner releases more eggs for the other to fertilize, as if mutual trust were increasing, whereas a fish that tries to play the male role twice in a row is dismissed by its partner to find another mate and begin the process of confidence building all over again.

Cooperation among members of a chimpanzee group is also based in large part on reciprocal altruism (de Waal, 1996). The community of interest among a group's chimpanzees is based on two fundamental features. First, a chimpanzee is in danger outside a group: it needs to belong to one. Second, a group's effectiveness depends on all its members. Thus, all must accommodate, even the dominant, because without his fellow members the dominant would be alone (W.J. Smith as cited in Leigh and Rowell, 1995). In captive groups, chimpanzees help those who have helped them, and they retaliate against those who have attacked them or failed them in time of need. Chimpanzees who are most generous to others when they obtain food are most likely to be given food when they beg for it. Chimpanzees' strategies of deception show that they are sufficiently self-aware that they can predict another's behavior by "putting themselves in the other's shoes." A chimpanzee who has supported another in a fight expects support from that other if it is attacked in consequence, and it will show anger if that support is not forthcoming.

Chimpanzees, however, seem to have a sense of justice (defined as what promotes the group's common good) that transcends reciprocal altruism (de Waal, 1996). Females may gang up on an alpha male who is taking excessive revenge on a subordinate. The group supports alpha males who mediate fairly in disputes, protecting lower ranking animals. If an alpha male always favors his allies when he interferes in fights, females will keep him from interfering. Indeed, alpha males retain their dominance by consent of the dominated. Finally, chimpanzees try to reconcile with animals whom they have just attacked, while the group noisily celebrates such reconciliations. Because fights endanger the welfare of the whole group, reconciliations serve the "common good," including that of the reconciler, who needs its fellow group members.

Cooperation Involving Brief Exchanges

The forms of cooperation discussed so far are long-term partnerships. Many other forms of cooperation involve brief exchanges analogous to those between shoppers and storekeepers in large cities (Leigh, 2010b). In many species, sexual

reproduction involves matings between individuals that will never meet again. Among plants, the bee that takes pollen from one plant to another of its species, may move on to different species. Just as shoppers compete for bargains and storekeepers for shoppers, so animals compete for the best mates and flowers for effective pollinators. Cooperation involving such brief exchanges has played a crucial role in evolution. Sexual reproduction made possible the evolution of genetic systems designed to facilitate adaptive evolution. Employing animals to pollinate their flowers and disperse their seeds enabled young to escape their parents' specialized pests and pathogens without sacrificing genetic variation, and to divert resources from defense to fast growth, allowing flowering plants to replace conifers (Leigh, 1999). How do partners in these brief exchanges keep the risk of being cheated low enough to make these exchanges profitable? We do not yet know. This question is particularly urgent since the ancestors of pollinators were pollen thieves or seed predators, and the ancestors of seed dispersers were likewise seed predators (Leigh, 2010b).

Indeed, such brief encounters offer no opportunity to punish partners that cheat, or supply inefficient or substandard goods. To avoid being cheated, individuals must try to choose more cooperative partners and exclude non-performers. Individuals share a common interest in mating with others of their own species (Fisher, 1930), but not all males of their species are equally suitable mates. Females of promiscuous species judge the suitability of courting males by criteria ranging from the size, beauty, and elaborateness of the structure a male bowerbird builds and defends from other males or the capacity for sustained, vigorous flight of a courting sulfur butterfly to the bright plumage of a healthy cock-of-the-rock. In these brief exchanges, however, a male's only interest is that his mate devote maximum effort on his young, even if this lowers her expected lifetime reproduction. Once copulation begins, a male may inject substances meant to keep her from mating with other males and to drug her into devoting all possible effort to his young. The female must evolve a variety of ways to parry these threats. And indeed, even after copulation starts, females of many species can prevent the copulating male's sperm from fertilizing their eggs (Eberhard, 1996). Despite these conflicts and hazards, all many-celled plants and animals descend from sexually reproducing ancestors, as if sexual reproduction were needed to evolve large, complex organisms. Most species of eukaryote, moreover, reproduce sexually, at least occasionally.

Similarly, plants use their flowers' design to try to choose their pollinators. Different rewards – resin, musk, perfume – attract different pollinators. The location of the reward within the flower (is it easily reached, or are specialized structures required to reach it?) and the flower's shape (Does it offer the pollinator a place to land, or must it hover?) and color also restricts the range of animals attracted. Nonetheless, cheating is rife among both plants and potential pollinators. Large trees, or plants of common species, cannot afford to cheat, for pollinators could easily learn to avoid them, but whole groups of orchids, and many other rare plant species, use a stunning variety of ruses to attract animals to pollinate their flowers without providing them any reward for doing so. Similarly, in at least some plant species, most flowers are robbed of at least

some of their nectar by animals that do not pollinate them. Despite the risks of cheating, most plants, especially in the tropics where competition is most intense, employ animals to pollinate their flowers (Leigh, 2010b).

Mutualisms of brief exchange are therefore essential for both evolutionary progress and ecosystem function. Nonetheless, we do not yet know how participants in these exchanges reduce the risk of being cheated to levels that do not threaten the profitability of participating in them.

Cooperation and the Common Good

Cooperation evolves only if there is genuine community of interest among the potential partners. In his *Politics*, Aristotle expressed this point very clearly: States whose constitution and social organization serve the common good more nearly are less susceptible to overthrow by popular revolution or factional putsch. Often, a common interest permits mutualisms to develop that lack any means of enforcement. However, even coreplication of host and symbiont (whereby symbionts can propagate only to the offspring of the host), such as that maintaining the mutualism between eukaryotic cells and their organelles, will not create a stable mutualism if host and symbiont do not share a stable common interest.

Mixed-species bird flocks are examples of mutualisms without enforcement (Leigh and Rowell, 1995). A typical Neotropical mixed flock contains one pair each of several “nuclear species,” some with attendant young. Adults of these nuclear species jointly defend a common territory. As the flock progresses regularly over its territory, certain birds with smaller territories join the flock as it passes through them, whereas other birds with larger territories move from flock to flock. Each species of bird eats different food, or feeds in different types of places, as if to minimize competition among flock members. The advantage of a flock is more eyes to watch for predators and more birds to “mob” a predator when need be (Moynihan as cited in Leigh and Rowell, 1995). Even an alarm signal benefits its giver – not only by helping to keep safe the group on which it depends but also by informing a potential predator that, since it has been seen in time to be avoided, it might as well go elsewhere. This mutualism of seemingly unenforced common interest has caused the evolution of certain colors and behaviors among members of certain mixed flocks (Moynihan, 1998).

One of the most striking mutualisms of the tropical forest is that between fig trees and their pollinating wasps (Herre, 1996). Each fig fruit is a flowerhead turned outside in to form a ball, lined with flowers on the inside, with a hole at one end. Each fruit is pollinated by one or more female wasps. These enter the fruit, pollinate its flowers, and lay eggs in up to half these flowers. Each wasp’s larva grows within a single fig seed. When a fruit’s adult wasps “hatch,” they mate among themselves and the fertilized females fly out in search of new trees to pollinate.

These pollinator wasps are parasitized by nematodes. In some fig species, each fruit is pollinated by several wasps, each carrying nematodes into the fig. The young of these different nematodes compete to enter the fertilized females leaving the fig, reducing the wasps’ ability to reach other figs, and their reproductive success should they reach one. In other, “single-foundress” fig species, almost every fruit is pollinated by a

single wasp. In these species, nematodes can only infect the young of their current host. Because of this coreplication, their reproductive success depends on that of their host. Selection thus favors nematodes which minimize the damage they inflict on their host. Such nematodes may sometimes enhance their host’s reproduction.

Coreplication shaped a stable mutualism between eukaryotic cells and their organelles, which persists in those few species whose members receive organelles from both parents. Nonetheless, coreplication of wasps and nematodes in single-foundress fig species has had no such effect. Some fig species with several pollinators per fruit are descended from single-foundress species. Nonetheless, their nematodes have reverted to the status of damaging parasites. They must lack a stable community of interest with their host wasps (Herre, 1993).

Another striking mutualism involves reef-building corals and their zooxanthellae, the symbiotic algae that supply them with carbohydrates in return for nutrients and a place in the sun. Many of these corals call their zooxanthellae from the surrounding water rather than inheriting them from their mothers by mutualism-enforcing coreplication. Wasps which inherit their nematodes from several hosts apiece suffer grievously from these parasites. Multiple origins of a coral’s zooxanthellae do not disrupt the coral–algal mutualism, presumably because the complementation of functions between corals and their zooxanthellae establishes an effective community of interest between these organisms. Community of interest makes the mutualism, not the breeding system.

Similarly, cooperation does not outlive the community of interest among its partners. When a coral ceases to benefit from its zooxanthellae (as often happens when the seawater becomes too warm), it expels them. When the queen dies in a colony of the social wasp *Metapolybia aztecoides*, no one member of the colony can lay enough eggs to maintain the colony’s pool of workers. Several would-be queens thus join forces to undertake this task. Practice, however, increases their egg-laying rate. When the reproductives no longer need each other, they fight it out for the profits of their cooperation (West-Eberhard, 1978). In summary, a defensible community of interest among the potential partners is the one thing needful for the evolution of cooperation. Coreplication, social system, reciprocal altruism, etc. can only affect enduring cooperation if there is a genuine community of interest among the potential partners.

Why is Cooperation so Crucial to Progressive Evolution?

Cooperation has allowed the successive formation of more complex and effective wholes from parts already tested by natural selection (Maynard Smith and Szathmáry, 1995). Moreover, wholes composed of modules already adapted to respond “constructively” to challenging circumstances are more capable of further adaptive evolution (Gerhart and Kirschner, 1997). Finally, the conflicts between selection at different levels, and the mechanisms by which these conflicts are controlled or suppressed, represent a series of distinctive footprints of the decisive role played by natural selection in

macroevolution. Indeed, study of the role of mutualism in evolution allows evolutionary history to testify decisively to the mechanisms of evolution.

Cooperation and the Major Transitions of Evolution

Cooperation played a crucial role in all the major transitions of evolution. Perhaps the first of these transitions, almost effaced by the mists of time, was the transformation of nucleic acid molecules which replicated themselves by parasitizing protein-based metabolism into genes programming the metabolism and development of discrete organisms (Dyson, 1985). Whether Dyson is correct or not, the origin of life as we know it did involve the transformation of mutually dependent genes into coherent genomes (Maynard Smith and Szathmáry, 1995). Later transitions include the evolution of bacterial cells containing a variety of smaller parasitic and commensal microbes into genuine eukaryotes (Margulis, 1993); the evolution of sexual reproduction, whereby two individuals cooperate to produce offspring more varied than either could alone (Maynard Smith and Szathmáry, 1995); the evolution of meiosis, which ensures an appropriate apportionment of the genes of a diploid cell to its haploid descendants (Maynard Smith and Szathmáry, 1995); the evolution of complex, multicellular organisms (Buss, 1987); and the evolution of animal societies (Leigh and Rowell, 1995).

All these transitions involve entities cooperating toward achievements which no one entity could accomplish unaided. Many of these transitions, such as the evolution of eukaryotes, metazoans, and complex insect societies, transformed groups of formerly independent entities into coherent, integral wholes. Insofar as evolutionary progress has occurred, the evolution of cooperation has made it possible.

Cooperation, Modularity, and Evolvability

To show how complex systems might evolve, Herbert Simon (1962) compared two watchmakers, Hora and Tempus. Hora put together a watch by making subassemblies of 10 parts apiece and then combining them into 2d-level assemblies of 10 subassemblies apiece, and so forth, until her watch was finished. Tempus would try to put together a watch without benefit of subassemblies. Both were subject to interruptions. An interruption forced Tempus to begin his watch again from scratch, whereas it forced Hora to begin her current subassembly again. As a result of her subassemblies, only Hora could finish watches.

The relevance of this parable to evolution is that cooperation can lead to combining preexisting “subassemblies,” each already tested by natural selection, into larger, more effective wholes (Simon, 1962; Dyson, 1985). Cooperation thereby allowed the evolution of complex organisms by manageable stages.

Moreover, when cooperating entities share a common interest strong enough for selection to transform groups of cooperators into better integrated, more effective wholes, the resulting combines benefit from two properties. First, the selfinterested adaptability of the component entities makes for a more effective and adaptable combine. Second, the

adaptability of its components enhances the combine’s capacity for adaptive evolution.

The first of these propositions is illustrated by the behavior of the oldest of intracellular organelles. The microtubules and centrioles (centrosomes) of eukaryotic cells, responsible for the “asters” and “spindle” that form during mitosis and meiosis, are not programmed by nuclear DNA. Instead, these organelles appear to be remnants of spirochetes which invaded the ancestors of their hosts countless ages ago (Margulis, 1993). When a cell divides in mitosis, the centriole, just outside the nucleus, divides first, and its two descendants move to opposite sides of the nucleus. Microtubules grow out from the centrioles, forming asters. A microtubule quickly dissolves unless it encounters a part of a chromosome called a “kinetochore,” which stabilizes a microtubule touching it. This “random exploration” by microtubules allows chromosomes to be attached to their respective asters in a few minutes, accomplishing the essential first step in apportioning a complete set of chromosomes to each daughter cell (Gerhart and Kirschner, 1997). At the level of cells within organisms, the generation and multiplication of a great variety of “T cells” allows selection for and mass production of those antibodies required to protect their organism from disease (Gerhart and Kirschner, 1997). At the level of organisms within societies, the search by foraging honeybees for new sources of food and the communication of successful searches to the hive, thereby recruiting other foragers to the newly found food, allow honeybee colonies to allocate foraging effort effectively (Seeley, 1995). At all three levels, forms of random exploratory search, conjoined with mechanisms rewarding success, play a crucial role in the development of well-adapted morphology and behavior. Search by quasiautonomous organisms often serves these purposes more effectively than more centrally controlled processes (Gerhart and Kirschner, 1997).

Adaptability of cells and tissues greatly increases the probability that a major change, genetic or environmental, will not prove lethal. E.J. Slijper described a goat born without forelegs. This goat learned to hop about like a kangaroo. To suit this goat’s peculiar two-legged hop, its hind legs became enlarged, its spine became curved and the sizes and shapes of its vertebrae changed, and the sizes and points of attachment of many muscles and ligaments also changed. These adjustments testify to the adaptability of this goat’s cells and tissues. Similarly, N. Smythe (as cited in Leigh, 1999) was able to create a social strain of pacas, otherwise fiercely territorial animals, by rearing one generation of young under special conditions. These young passed on their new social “traditions” to their descendants. The adaptability of animals, developmental and social, allows them to adapt to some very unusual circumstances.

Cooperation and Unmistakable Footprints of Natural Selection

The author has shown how several evolutionary transitions involved smaller parts combining into larger, more integral wholes. Thus, certain parasites and commensals of bacteria were transformed into organelles of eukaryotic cells, certain multicellular aggregates were transformed into coherent

multicellular individuals, and certain insects which lived together in groups were transformed into units of cohesive insect societies with a single reproductive and complex division of labor.

A trace of each of these transitions is left in the potential conflicts between the erstwhile parts and the whole they formed. Competition between organelles inherited from different parents can injure their hosts. The spread of cancerous cells can kill the individual to which they belong. Worker bees can lay eggs of their own rather than help their queen.

How a transition occurred is often revealed by the mechanisms which suppress conflicts between the resulting whole and its parts. Most organisms are designed to ensure uniparental transmission of organelles, thereby preventing competition between organelles from different parents and ensuring that the reproduction of organelles depends utterly on the reproduction of their hosts. In most metazoan species, sexual reproduction ensures that each individual is genetically unique, but that individual's cells are genetically identical save for the accidents of somatic mutation, a circumstance that ensures that selection discriminates among individuals and not the cells within a single individual. The other means by which metazoans reduce the threat of "rebel" cell lineages – sequestration of the germline (so that cancers of the body cannot be passed on to offspring), maternal control of the early stages of development of her young, and so on – are paralleled by the means whereby queens of complex insect societies maintain harmony within their colonies.

Since these conflicts are suppressed by the very mechanisms that joined the parts into larger wholes, the mechanisms involved represent unmistakable footprints of the critical role natural selection played in these transitions – the most important events of macroevolution. The conflicts involved in each such transition, and the means by which they are suppressed, reveal the historical path of evolution and the selective mechanisms that directed it. Thus, study of the role of mutualism in evolution enables evolutionary history to testify to the mechanisms of this evolution (Maynard Smith and Szathmáry, 1995).

Cooperative Endeavor and Ecosystem Evolution

In our concern with how natural selection of random mutation can yield precise, complex adaptation, we easily forget that organisms evolve in ecological communities. The genius of Archimedes, Newton, Darwin, and Einstein could only be expressed in an urbanized, literate civilization with a diversity of occupations and an audience able to appreciate and benefit from their discoveries. Similarly, social insects, energetic warm-blooded mammals, and flowering plants dependent on animal pollinators could only evolve in diverse ecosystems with intense predator and herbivore pressure and a great variety of resources. In Madagascar, a famous orchid, *Angraecum sesquipedale*, attracts high-performance hawkmoths to pollinate its flowers; these moths need a 30-cm-long proboscis to reach its nectar. On the far smaller island of Réunion, where diversity is far lower and competition far less intense, the orchid *Angraecum cadetii*, descended from Malagasy invaders

closely related to *Angraecum sesquipedale*, has a much simpler flower, offers a poorer reward, and attracts a flightless cricket as its only pollinator (Leigh, 2010b).

Indeed, just as human society could not progress without individuals' innovations in fields ranging from agriculture and transport to communication and politics, so modern ecosystems could not evolve without the major transitions of evolution. Thanks to a succession of crucial innovations such as those just mentioned, human societies have evolved many different occupations (ways to make a living), high economic productivity, intense competition, and complex forms of interdependence. The array of human laws devoted to preventing cheating on various forms of cooperative endeavor – laws against violating contracts, embezzling, fraud, bribery, and so on – reflect how much economic productivity and social welfare depend on various forms of cooperation. The role in ecosystem evolution of the major transitions of evolution, each centering on a new form or expression of cooperation, suggests that ecosystem productivity and diversity depend utterly on cooperative endeavor (Leigh, 2010b).

Eukaryotes, organisms whose cells have nuclei, evolved when natural selection transformed α -proteobacteria of an aerobic, parasitic species that invaded individuals of an archaeobacterial species into mutualistic mitochondria (Davidov and Jurkevitch, 2009). All eukaryotes descend from this one mutualistic symbiosis. This mutualism led to the evolution of meiosis, mitosis, and orderly sexual reproduction. Mitochondria lost many of their genes, and other genes were transferred to their hosts' nuclei, but they retained their ability to produce energy-rich adenosine triphosphate. These mitochondria provided the energy their hosts needed to replicate nuclear genomes many times larger than any bacterium's, and to express these genomes' genes. These large genomes allowed the evolution of complex, multicellular organisms (Lane and Martin, 2010).

Symbioses between corals, whose polyps snare small animals from the surrounding water, and zooxanthellae living in these polyps and supplying them with carbohydrates in return for the fertilizing wastes from the digestion of the animals the polyps caught, allowed coral reefs to evolve. The first and largest coral reefs formed off tropical shores in the Devonian. They have disappeared and reformed many times since. The sessile bivalves that replaced reefs during the warmest periods of the Mesozoic also harbored symbiotic algae. Finally, symbiotic cyanobacteria allowed filter-feeding sponges to colonize those parts of Australia's Great Barrier Reef furthest offshore, where the water is clearest and the plankton sponges live on is most scarce (Leigh, 2010b). The reefs resulting from this symbiosis are the most diverse, complex, and beautiful of marine ecosystems.

Employing animals as pollinators and seed dispersers was crucial to evolving today's productive, diverse tropical rain forests. Employing animals as pollinators enabled the understory weeds that gave rise to flowering plants to maintain genetic variation even when their species was made rare by specialized pests or pathogens. Moreover, when a species becomes so rare that many of its members escape the attentions of its specialized pests, selection favors diverting resources from antiherbivore defense to fast growth. During the forty million years after flowering plants first appeared, 140 million

years ago, they evolved efficient systems for moving water from the soil through roots and stems to the leaves, enabling them to invade sunny habitats. In the end, leaves of flowering plants averaged four times the vein density (length of veins per mm² of leaf) of conifers, which doubled their photosynthetic capacity and potential transpiration rate. Because flowering plants also employed animals to disperse their seeds beyond the reach of their parents' pests, the stage was set for a diverse set of fast-growing flowering trees to replace a far less diverse set of slower-growing, better-defended, wind-pollinated conifers in all but the least favorable habitats. Moreover, the abundant transpiration of flowering plants has increased rainfall and expanded the domain of tropical rain forest. Thus mutualism has made possible the most diverse, productive and magnificent of the earth's terrestrial ecosystems (Leigh, 1999, 2010b; Brodribb and Field, 2010; Lane and Martin, 2010).

Glossary

Biological carbon pump Describes the biologically mediated transfer of carbon from the euphotic zone to the ocean's interior, maintaining a vertical gradient in inorganic carbon concentrations. Major processes involved in the pump include photosynthetic consumption of inorganic carbon and production of organic matter in the euphotic zone, gravitational settling of particulate organic matter, and subsequent remineralization of organic matter back to inorganic carbon at depth in the ocean.

Chemoorganoheterotrophy A form of metabolism that relies on oxidation of organic compounds for energy, reducing equivalents, and carbon.

Diazotroph Free-living or symbiotic bacteria or archaea that are capable of reducing N₂ to a biologically utilizable form of nitrogen (N), ammonia (NH₃).

Dinitrogen (N₂) fixation Dinitrogen (N₂) is the most abundant form of nitrogen (N) in the atmosphere. It is unavailable to most microorganisms because it consists of a stable N≡N triple bond, and breaking this molecule requires substantial energy. Only selected microorganisms, termed "diazotrophs," have evolved the capacity to fix N₂ that is the conversion of N₂ to ammonia (NH₃), a biologically more available source of nitrogen (N) to many microorganisms. N₂ fixation is catalyzed by the enzyme nitrogenase and is an energy-expensive process; 16 ATP molecules and eight reducing equivalents are required to reduce N₂ to 2 NH₃.

Euphotic zone Is the uppermost or "well-lit" layer of the ocean in which there is sufficient light energy available to support net photosynthetic growth. The euphotic zone extends to a depth where light intensity falls from 0.1% to

1% of that at the surface and in the open sea generally varies from <50 m to ~200 m.

Heterocyst The site for N₂ fixation in some species of filamentous cyanobacteria. A heterocyst is a differentiated cell that may be present terminally or intercalary. It lacks photosystem II, but photosystem I is present, providing a means to generate additional energy (ATP) required to fuel N₂ fixation.

New versus regenerated production Depending on the source of nitrogen (N), primary production in the sea can be divided into "new" and "generated" production. Production maintained by assimilation of new sources of N to the euphotic zone, such as nitrate (NO₃⁻) or N₂, is referred to as "new production," whereas production derived from recycling of nutrients within the euphotic zone such as via the uptake of ammonia (NH₄⁺) or dissolved organic N is termed "regenerated production."

Nitrogenase A metalloenzyme complex that catalyzes the process of N₂ fixation. The nitrogenase enzyme consists of two highly conserved protein subunits: An iron protein (Fe) known as "dinitrogen reductase" and a molybdenum-iron protein (MoFe) known as "dinitrogenase." Nitrogenase is sensitive to the presence of oxygen (O₂), becoming irreversibly inhibited at high O₂ concentrations.

Photolithoautotrophy A form of metabolism that depends on light as an energy source, inorganic compounds (e.g., H₂O, H₂S) for reducing equivalents, and CO₂ as a source of carbon.

Photoorganoheterotrophy A form of metabolism that utilizes light as a source of energy and organic compounds as sources of both reducing power and carbon.

Introduction

Earth's largest ecosystems are found in the sea, and these massive habitats comprise vast reservoirs of planktonic biodiversity. The combined metabolic activities of diverse planktonic communities make the oceans globally significant bioelemental reactors. Numerous selective forces collectively shape extant microbial diversity, and the emergence of specific traits offer glimpses into successful strategies for adapting to life in the sea. The wealth of biodiversity found in contemporary marine ecosystems reflects a long history of evolutionary adaptations, and some of the best examples of this selective adaptation can be found among microorganisms catalyzing the nitrogen (N) cycle. N is an essential element for life required for biosynthesis of nucleotides, amino acids, proteins, and nucleic acids, but bioavailable forms of N are

often found in vanishingly low concentrations (nanomolar) in the euphotic zone of the open sea. In these habitats, biological demand for N often outpaces its supply, and the availability of N restricts planktonic growth and limits the capacity of these ecosystems to support biomass. Ironically, both the atmosphere and oceans hold a nearly inexhaustible reservoir of N in the form of dinitrogen (N₂). However, only a select group of microorganisms termed "diazotrophs" are capable of utilizing this pool of N as a nutrient resource. By converting N₂ to ammonia (NH₃), these microorganisms constitute a key microbial functional guild: the metabolic activities of these organisms supply new N to otherwise N-depleted ecosystems, making them fundamental to plankton ecology and ocean biogeochemistry.

Microorganisms catalyze nearly all of the major processes in the N cycle. The ability of various N-containing compounds

to accept or donate electrons situates N as an important participant in numerous biologically catalyzed oxidation–reduction reactions. The N cycle includes processes that utilize N as a nutrient resource in support of cellular biomass production (assimilatory processes) and those that rely on N compounds as either electron donors or acceptors (dissimilatory processes). All of these processes collectively interact to govern the sizes of N inventories and the movement of N from one pool to another in the sea. Among the assimilatory N cycle processes, only N₂ fixation is capable of introducing new bioavailable N to an ecosystem. Globally, biological N₂ fixation is estimated to supply ~250 Tg N per year, with ~50% of that input occurring in the open ocean (Gruber and Galloway, 2008). Introduction of new N via N₂ fixation is countered by various removal processes that result in production of the gaseous products N₂ or N₂O; these removal processes include denitrification (dissimilatory reduction of nitrate and anaerobic ammonia oxidation) and to a lesser extent nitrification (via production of nitrous oxide).

Marine N₂ fixers appear most abundant in tropical and subtropical ecosystems where upper ocean temperatures typically vary between ~18 °C and 30 °C and concentrations of fixed N are low relative to other bioessential nutrients. In the nutrient-poor regions of the upper ocean, activities of N₂-fixing microorganisms provide an important source of N fueling plankton production. N₂-fixing microorganisms are both responsive to and modifiers of their environment. In addition, the process of N₂ fixation is highly regulated at the genetic level and can respond rapidly to fluctuations in the environment. Intriguingly, diazotrophs are frequently found at

very low population abundances relative to other microorganisms growing in these waters (Figure 1). Nonetheless, through their ability to control the availability of an essential limiting resource, diazotrophs constitute a keystone functional role in various regions of the ocean. Introduction of fixed N to an otherwise N-starved ecosystem results in a cascade of responses, altering food web ecology, biomass productivity and standing stocks, and ultimately the carbon (C) sequestration potential of the ecosystem. The fate of N introduced by N₂-fixing microorganisms and its consequences on ocean biogeochemistry have been active areas of research for decades, but much less is known about the ecology and diversity of the organisms that underpin the process. The vast majority of ocean habitats are remote and largely inaccessible, resulting in chronic undersampling of marine diazotroph habitats.

The marine N₂-fixing microorganisms we understand best are those most easily recognized under a microscope and amenable to isolation and cultivation. Much of our understanding of marine diazotroph physiology has developed based on laboratory studies of cyanobacteria belonging to the genera *Nostoc*, *Trichodesmium*, *Crocosphaera*, and *Nodularia*. However, the diazotroph guild is populated by diverse groups of microorganisms with equally diverse metabolic capabilities. Many of these organisms have no cultivated representatives from which to build our understanding of their physiological behavior, metabolic flexibility, or sensitivity to perturbation. Like many major advances in microbial ecology over the past decade, the study of marine diazotrophs has been greatly facilitated through fusion of cultivation-independent molecular biology techniques with biogeochemical rate measurements.

Figure 1 Habitat characteristics of the euphotic zone in the oligotrophic North Pacific Ocean. Vertical distributions of inorganic nutrients (NO₃⁻ and PO₄³⁻, (a)) and abundances of prominent groups of planktonic microorganisms (b); also depicted is the depth to which 1% of the incident irradiance penetrates (dashed line in (a)). Diazotroph abundances estimated based on quantitative PCR-based determinations of *nifH* gene copies. Het. Bacteria refers to presumed heterotrophic picoplankton.

Perhaps nowhere has the marriage of these disparate tool kits yielded more unique insights than to our understanding of the microbes driving the N cycle. Such work has begun to transform ecological studies of marine microorganisms, allowing mapping of organisms onto processes, and providing new information on rates of biogeochemical transformations mediated by specific microorganisms (Zehr and Kudela, 2011). In this chapter, we highlight the importance of biological N₂ fixation as a key determinant of biogeochemical cycling and plankton biology, with a focus on describing some of the recent advances on the diversity and ecology of N₂-fixing microorganisms in the open sea.

Biodiversity of N₂-Fixing Microorganisms in the Sea

Marine diazotrophs are morphologically, genetically, and metabolically diverse. They have been reported to occur in marine habitats ranging from sea ice to warm tropical seas, and to occur as both free-living organisms or associated with other organisms through various forms of symbiotic relationships. In the oceans, these organisms appear most abundant throughout the low-nutrient, high-light regions of the subtropical ocean gyres that include ~40% of the surface area of the planet. Much of our understanding of marine diazotroph diversity has derived from advances along several avenues of research that include application of cultivation-independent molecular techniques, biogeochemical rate measurements at the level of single cells to whole communities, and cultivation-dependent cell isolations and manipulative laboratory-based model diazotroph systems.

Nitrogenase and *nifH*

The capacity for N₂ fixation is widely distributed among members of bacteria and archaea; to date, there are no reports of N₂ fixation by eukaryotes. The maintenance of diverse microbial lineages performing N₂ fixation may reflect the importance of this process to ocean ecosystems. In an environment where fluctuations in habitat conditions are prevalent and comprise important selective forces, functional redundancy may ensure that critical ecosystem services are retained in the face of variations in population structure.

N₂-fixing microorganisms utilize the enzyme complex nitrogenase to catalyze the reduction of N₂ to NH₃; the reaction can be described as

The conventional nitrogenase enzyme consists of two transiently interacting protein clusters: a tetraheterodimer molybdenum–iron containing protein called “dinitrogenase” and a homodimer iron–sulfur protein called “dinitrogenase reductase.” Some organisms may also possess alternative nitrogenases in which molybdenum in dinitrogenase is substituted by vanadium, or, in other cases, this protein contains iron only. Dinitrogenase appears to be the substrate-binding protein, whereas the role of dinitrogenase reductase is to facilitate the transfer of electrons needed to reduce dinitrogenase. Nitrogenase is rapidly inactivated in the presence of

oxygen (O₂), and microorganisms that catalyze the reaction have evolved various strategies for establishing anoxic conditions necessary to protect the enzyme from O₂. The high activation energy required to break the triple bond in N₂ and the subsequent reduction of N₂ to NH₃ are energy- and reductant-demanding processes. Sixteen moles of ATP and eight electrons are required for every 2 mol of NH₃ produced by the reaction. The evolution of hydrogen (H₂) by the reaction represents a potential reductant sink; however, many N₂-fixing microorganisms utilize hydrogenases to internally recycle the H₂. The key role of iron (Fe) as a co-factor in this enzyme system, together with low supply of Fe to large regions of the sea, has led to the suggestion that Fe might be a key element limiting N₂ fixation in many ocean ecosystems.

The nitrogenase enzyme complex is encoded by a suite of genes in the *nif* operon; dinitrogenase is encoded by *nifD* and *nifK* genes, whereas dinitrogenase reductase is encoded by the *nifH* gene. The process of N₂ fixation is highly genetically regulated through transcriptional and translational modification of the *nifHDK* gene products. Such strict regulation has been hypothesized to minimize energy losses incurred if the gene product was translated to a functional protein under conditions not conducive to N₂ fixation – for example, in the presence of O₂ (Zehr and Paerl, 2008). The evolutionarily conserved nature of the *nifH* gene has been capitalized on for its utility as a molecular target for studying N₂-fixing microorganisms. Analyses of the phylogeny of *nifH* genes reveal four deeply branching gene lineages (Figure 2(a); Zehr *et al.*, 2003). One of these lineages (termed Cluster IV) derives from *nif*-related gene families, whereas the remaining three clusters represent *nifH* genes from widely diverse groups of prokaryotes. Among the Cluster I *nifH* genes are representatives of both the conventional molybdenum-containing nitrogenases and selected alternative vanadium-containing nitrogenases. Cluster II contains microorganisms encoding the alternative nitrogenases (those containing Fe only) as well as selected groups of N₂-fixing archaea. Cluster III includes numerous and diverse anaerobic *nifH*-containing microorganisms. The vast majority of cultivated *nifH*-containing marine microorganisms are found among Cluster I; this cluster includes the cyanobacteria as well as a large proportion of N₂-fixing proteobacteria (including the α -, β -, γ -, and ϵ -proteobacteria).

Despite the value of metagenomic techniques to identify physiological and metabolic capabilities among environmental microorganisms, these approaches have provided only limited information on marine diazotrophs. In large part this stems from the low population abundances of these organisms, making them highly underrepresented in these large-scale sequencing efforts (Johnston *et al.*, 2005). However, *nif* genes have been retrieved (albeit in very low numbers) from selected metagenomic sequence libraries from ocean plankton and analyses of these sequences have provided new insights into evolutionary strategies and selective adaptations by marine N₂ fixers. Metagenomic sequence analyses from naturally occurring populations of *Crocospaera* in both the Pacific and Atlantic Oceans led to the conclusion that these diazotrophs demonstrate remarkable gene conservation (Zehr *et al.*, 2007), a finding that contrasts studies on more-abundant non-N₂ fixing oceanic cyanobacteria (e.g., *Prochlorococcus*). These results suggest oceanic cyanobacterial diazotrophs may

Figure 2 Phylogenetic relationships among nitrogenase (*nifH*) genes (a). Representative groups of bacteria and archaea from each of the deeply branching clusters (I–IV) of genes are shown. Phylogenetic relationships and microscopy images of several major groups of *nifH*-containing cyanobacteria common to the subtropical oceans (b). Images include *Crocosphaera* (1), endosymbiotic heterocystous *Richelia* sp. shown inside the diatom *Rhizosolenia* sp. (2), and three morphologies of organisms belonging to the genus *Trichodesmium* (3). Microscopy images courtesy of Angelique White (Oregon State University).

undergo different selective pressures than their more abundant relatives and rely on different evolutionary strategies for survival.

Many of the advances in our understanding of the diversity of N₂-fixing microorganisms have derived from polymerase chain reaction (PCR) amplification of *nifH* genes from naturally occurring plankton communities. This approach has yielded sequence information, enabled new approaches to studying *nifH* diversity, and provided tools to quantify *nifH* gene abundances and gene transcripts in the sea. In large part as a result of PCR amplification, cloning, and sequencing efforts, there are currently more than 36,000 publicly available *nifH* gene sequences. This wealth of sequence information provides insight into numerous aspects of diazotroph diversity, including understanding how *nifH* genes have become so widely distributed among different groups of microorganisms and tailoring of molecular-based approaches to studies of specific groups of *nifH*-containing microorganisms.

Phenotypic and Genetic Diversity of Marine N₂ Fixers

Marine cyanobacteria are morphological diverse, including both unicellular and colonial organisms ranging in size across more than three orders of magnitude ($\sim 1 \mu\text{m}$ to $> 1 \text{ mm}$, **Table 1**). The ability to enact selective pressures as part of cultivation strategies (namely, N-free media and light) has yielded isolated representatives from many of the dominant lineages of oceanic N₂-fixing cyanobacteria. Arguably the best-studied marine cyanobacteria are members of the genus *Trichodesmium*; these non-heterocystous cyanobacteria exhibit a wide range of cell morphologies, growing as either single filaments (termed “trichomes”) or colonial aggregates of filaments (Capone and Carpenter, 1982). On average, each trichome contains ~ 100 individual cells, with each colony comprised of 100–200 trichomes (Letelier and Karl, 1996). *Trichodesmium* abundances vary widely (**Table 1**), with abundances occasionally very high ($> 10^5 \text{ cells L}^{-1}$) during large

Table 1 Characteristic features of various marine diazotrophs commonly found in tropical and subtropical ocean ecosystems

Organism	Cultivated representatives	Size range	Abundance (cells L ⁻¹)	Notable physiological features
<i>Filamentous cyanobacteria</i>				
<i>Trichodesmium</i> spp.	<i>T. contortium</i> , <i>T. erythraeum</i> , <i>T. hildebrandt</i> , <i>T. T. tenue</i> , <i>T. thiebautii</i> <i>K. spiralis</i> , <i>K. pelagica</i>	~ 10 µm–1 mm	ND–> 10 ⁵	Non-heterocystous, photolithoautotroph, bloom-forming, daytime N ₂ fixer, buoyancy control
<i>Richelia</i> spp.	<i>R. intracellularis</i>	~ 10–40 µm	ND–> 10 ⁶	Heterocyst-forming, photolithoautotroph, bloom-forming, endosymbiont of diatoms <i>Hemiaulus</i> spp. and <i>Rhizosolenia</i> spp., daytime N ₂ fixer
<i>Calothrix</i> spp.	<i>C. rhizosolenia</i>	~ 15–30 µm	ND–10 ³	Heterocyst-forming, photolithoautotroph, bloom-forming, epibiont of diatoms <i>Chaetoceros</i> sp., daytime N ₂ fixer
<i>Unicellular cyanobacteria</i>				
Group A	Uncultured	< 1 µm ^a	10 ³ –10 ^{5b}	Photoorganoheterotroph, presumed daytime N ₂ fixer, lacks photosystem II, possible symbiont
<i>Crocospaera</i> spp.	<i>Crocospaera watsonii</i> (WH0001, WH0002, WH0003, WH0004, WH0005, WH0006, WH0401, WH0402, WH8501, WH8504)	2–8 µm	10 ³ –10 ⁶	Photolithoautotroph, free-living, nighttime N ₂ fixer
Group C	TW3	4–6 µm	ND–> 10 ^{5b}	Photolithoautotroph, free-living, nighttime N ₂ fixer
<i>Non-cyanobacteria</i>	<i>Vibrio diazotrophicus</i> , <i>Klebsiella</i> , <i>Pseudomonas</i>	< 1 µm	~ 10 ² –10 ^{3b}	Chemoorganoheterotrophs, obligate and facultative anaerobes

^aSize estimated based on flow-cytometric cell sorting and size-fractionated QPCR results.^bAbundances estimated based on QPCR determinations of *nifH* gene copies, assuming one gene copy equals one cell.

blooms. Intensive cultivation efforts have yielded numerous laboratory isolates of *Trichodesmium*, including *T. thiebautii*, *T. erythraeum*, *T. tenue*, *T. hildebrandt*, and *T. contortium*. The genome of *T. erythraeum* also has been sequenced (7.8 Mega bases; Mb). In addition, organisms previously identified as belonging to the genus *Katagneme* (including *Katagneme spiralis* and *Katagneme pelagic*) are genetically so similar to *Trichodesmium* that it appears these organisms should in fact be considered members of this genus (Lundgren *et al.*, 2005), providing additional evidence of the phenotypic plasticity exhibited by *Trichodesmium*.

Another prominent assemblage of marine N₂ fixers includes various heterocyst-forming cyanobacteria. These filamentous cyanobacteria form 5–10 cell chains of vegetative (photosynthetically active) cells terminally bound by non-vegetative (lacking photosystem II) cells called “heterocysts.” The heterocyst forms the active site of N₂ fixation; the thick glycoprotein cell wall acts as a diffusion barrier for O₂, thereby protecting nitrogenase. Compared to freshwater or brackish waters, oceanic heterocystous cyanobacteria are relatively rare, but these organisms have been known as important contributors to open ocean N cycling for many years (Venrick, 1974; Carpenter *et al.*, 1999). Several distinct groups of oceanic heterocystous diazotrophs have been described,

including *Richelia intracellularis* and *Calothrix rhizosoleniae*, and the abundances of these organisms is highly variable, occasionally exceeding 10⁶ cells L⁻¹ during blooms (Table 1). Notably, these cyanobacteria are frequently observed in symbiotic relationships with various genera of oceanic diatoms. Among the best studies of these interactions are those involving *R. intracellularis* and diatoms belonging to the genera *Rhizosolenia* and *Hemiaulus*. *Richelia* forms intracellular symbiotic partnerships with these diatoms, providing fixed N to the hosts. However, it is unknown whether the cyanobionts benefit from these interactions, but such benefits might include exchange of nutritional or energy-demanding substrates, buoyancy regulation by the host, or protection from predation (Carpenter, 2002). Unlike the endosymbiotic relationships between *Richelia* and *Rhizosolenia* or *Hemiaulus*, *Calothrix* are often observed attached as an epiphyte to the spaces between chains of diatoms belonging to the genus *Chaetoceros*. *C. rhizosoleniae* has been isolated in culture without the host diatom, indicating the symbiosis is not obligate (Foster *et al.*, 2010). Moreover, consistent with these results, the genome of the isolate is relatively large (6.6 Mb) compared to obligate symbionts. Genetic analyses, based on various functional genes and ribosomal RNA genes, suggest that different groups of diazotroph symbionts form specific associations with the

diatom hosts. Such symbiotic interactions do not appear strictly limited to heterocystous cyanobacteria; the oceanic diatom *Climacodinium frauenfeldianum* also hosts presumed N₂-fixing unicellular cyanobacteria (Carpenter and Janson, 2000). How these symbioses develop and are maintained over generations remains largely unknown. Moreover, it remains unknown to what extent these symbioses have shaped the co-evolution of the diazotrophs and their hosts.

Unicellular organisms appear to comprise some of the most abundant and geographically dispersed groups of the marine N₂-fixing cyanobacteria (Moisander *et al.*, 2010). Research into the diversity and ecology of these microorganisms has been greatly facilitated by both cultivation-dependent approaches and application of various genetic tools. Initial surveys of oceanic *nifH* genes revealed the presence of sequence types that clustered phylogenetically among unicellular N₂ fixers. Subsequent studies revealed that the *nifH* sequence of one of these phylotypes was identical to *Crocospaera*, a unicellular cyanobacterium initially isolated in the mid-1980s but which had been largely overlooked in its potential contributions to marine N₂ fixation (Zehr *et al.*, 2001). Members of the genus *Crocospaera* are readily identified based on both their spherical morphology, size (2–8 μm in diameter), and brightly fluorescent characteristics of the pigment phycoerythrin. *Crocospaera* abundances are often reported between $\sim 10^3$ and 10^4 cells L⁻¹, with occasional blooms exceeding 10^6 cells L⁻¹ (Table 1). Several isolates of *Crocospaera* now exist, and the genome (6.2 Mb) of *Crocospaera watsonii* WH8501 has been sequenced. The strains exhibit some notable differences in morphology and physiologies, despite low apparent genetic variability. For example, examination of 10 strains of *Crocospaera* indicated that, despite minimal differences in rRNA genes and internal transcribed spacer regions, the strains varied in size, temperature optima for growth (ranging between 22 and 36 °C), and production of extracellular organic material (Webb *et al.*, 2009).

Subsequent studies in the Atlantic Ocean revealed the presence of *nifH* genes closely related to *Cyanothece* ATCC51142 (Langlois *et al.*, 2005) belonging to a N₂-fixing cyanobacteria termed “group C” (Foster *et al.*, 2007). The *nifH* gene abundances of these organisms were subsequently examined in the waters of the tropical Atlantic, suggesting that on occasion this organism could be relatively abundant ($\sim 10^5$ cells L⁻¹). Cultivation efforts in the western Pacific yielded heavily pigmented, 4–6- μm diameter cells whose *nifH* and 16 S rRNA genes cluster closely among group C and *Cyanothece*, respectively. These isolated aerobic diazotrophs (strain name TW3) actively fix N₂ at night (Table 1) and grow most rapidly at water temperatures ~ 30 °C, suggesting these organisms may be largely restricted to tropical waters (Taniuchi *et al.*, 2011).

A third group of unicellular N₂-fixing microorganisms, termed “group A,” was first identified based on *nifH* gene sequences. The *nifH* gene sequences of group A are also most closely related to the marine unicellular cyanobacterium *Cyanothece* sp. strain ATCC 51142. However, to date, no representatives of group A microorganisms have been isolated in culture. Information on these microorganisms mostly derives from PCR- and reverse-transcriptase PCR-dependent (including both 16 S rRNA and *nifH* genes) methodologies to examine their distributions and patterns of *nifH* gene

expression. Quantitative PCR (QPCR) based surveys revealed that the group A phylotype is often the most abundant ($\sim 10^5$ *nifH* gene copies L⁻¹) and widely distributed of the N₂-fixing cyanobacteria. A major breakthrough in our understanding of these organisms came from targeted flow cytometric cell sorting and subsequent metagenomic analyses of the sorted cell populations (Zehr *et al.*, 2008). This approach provided several important pieces of information about these uncultivated organisms: (1) they are small (~ 1 μm in diameter), (2) possess a highly reduced genome (1.44 Mb), and (3) lack a number of fundamental biosynthetic pathways (Zehr *et al.*, 2008; Tripp *et al.*, 2010). Notably absent from the genome of group A were genes required for inorganic C fixation, photosystem II, genes necessary for synthesis of purines and several amino acids; and nearly all the major genes required for a functional tricarboxylic acid cycle (Tripp *et al.*, 2010). The lack of these basic biosynthetic pathways suggests group A are likely symbionts, providing fixed N to hosts in exchange for the supply of fixed C substrates required for basic cellular biosynthesis.

The prevalence of different forms of diazotroph symbioses in the marine environment hints that mutualism is an important mode of existence in the open sea. Such observations should not be surprising – the majority of N₂ fixed in terrestrial ecosystems appears controlled by diazotroph symbioses. Symbiotic interactions involving many of the most common marine diazotrophs suggests we may need to revisit the prevailing notion that competition is the primary factor shaping adaptation in the nutrient-depleted upper ocean. The struggle to acquire nutrients in persistently oligotrophic ocean habitats also appears to select for cooperative interactions as an evolutionary strategy, although perhaps at the expense of rapid growth.

In addition to the cyanobacteria, diverse non-cyanobacterial diazotrophs have been reported from marine habitats, including representatives of the α -, β -, δ -, and γ -proteobacteria, *Chlorobi*, *Actinobacteria*, *Firmicutes*, *Spirochaetes*, and archaea. In the well-oxygenated waters of the open sea, many of the N₂ fixers identified through isolation or via genetic techniques appear related to facultative or obligate anaerobes although studies on the distributions and activities of these organisms in the open sea are lacking. Based on the limited surveys available for evaluating these non-cyanobacterial N₂ fixers, it appears these organisms are often found at low population abundances in the upper ocean ($< 10^4$ *nifH* gene copies L⁻¹). Nonetheless, the application of PCR-dependent methodologies has begun to provide important clues into the diversity of non-cyanobacterial N₂-fixing microorganisms, suggesting much greater diversity of these organisms than currently represented in culture collections. Amplification and sequencing of *nifH* genes from environmental samples collected from both oligotrophic and eutrophic ocean waters indicates that diverse bacterial lineages dwell in the sea, including those phylogenetically grouping among the Clusters I, III, and IV *nifH* sequences. Although there is relatively little known about the metabolic capabilities of these organisms or their potential contribution to N₂ fixation, they appear widespread (Riemann *et al.*, 2010). Several studies have found expression of *nifH* genes by various groups of non-cyanobacterial diazotrophs, suggesting an active role for these microorganisms in marine

N₂ fixation. Organisms phylogenetically affiliated with the Cluster I *nifH* phylotypes are the most common non-cyanobacterial diazotrophs, and they include members of the α -, β -, γ - and δ -proteobacteria. Among those, several *nifH* phylotypes clustering among γ -proteobacteria seem to be widespread, having been reported in clone libraries not only from the Pacific and Atlantic Oceans but also from the Arabian and Baltic Seas (Langlois *et al.*, 2005). In addition, *nifH* genes similar to those belonging to obligate anaerobes (most closely related to phototrophic green-sulfur bacteria and spirochetes) contained within the Cluster III *nifH* sequences have been retrieved from *nifH* gene clone libraries in the North Pacific and Atlantic Oceans. These *nifH* gene sequences appear most abundant ($\sim 10^3$ – 10^4 *nifH* copies L⁻¹) in the dimly waters of the lower euphotic zone. Nevertheless, our current understanding of the ecological processes that control these presumed N₂-fixing microorganisms is woefully lacking and ripe for future progress.

Metabolic and Physiological Diversity

Oceanic diazotrophs include aerobes and anaerobes, phototrophs and chemotrophs, autotrophs and heterotrophs, in addition to various hybrid modes of metabolism. The process of N₂ fixation has a high demand for energy and reducing power and exhibits extreme sensitivity to O₂. The biosynthesis of the metalloenzyme nitrogenase places unique nutritional demands on these cells, including requirements for specific trace metals often found in vanishingly low concentrations in the sea. Furthermore, in many organisms the presence of ammonium (NH₄⁺) suppresses N₂ fixation due to transcriptional and post-translational regulation of nitrogenase. The fairly stringent demands imposed by a diazotrophic lifestyle greatly narrow the window of available niche spaces able to support the growth of these organisms. Some of the most notable examples of physiological diversification among the marine N₂ fixers are found in the way they acquire energy, harvest nutrients, and protect nitrogenase from O₂, suggesting these selective forces factor prominently into shaping the evolutionary history of these organisms.

Given the relatively high energetic demands of N₂ fixation, it should not be surprising to find that many of the most common ocean diazotrophs utilize sunlight as a relatively plentiful source of energy in the sea. Such organisms include obligate and facultative photolithoautotrophs and photoorganoheterotrophs. Oxygenic photolithoautotrophic N₂-fixing cyanobacteria have received considerable attention, with much of this focused on how these microorganisms protect nitrogenase from O₂ evolved during photosynthesis (Gallon, 1992). Most of these organisms rely on one of two strategies: (1) spatial separation of photosynthesis and N₂ fixation, or (2) temporal separation of these processes (Paerl, 1990). In the case of heterocystous cyanobacteria, nitrogenase is confined to the heterocyst; these specialized nonvegetative cells lack photosystem II but retain photosystem I, thereby enabling cyclic photophosphorylation to provide energy to fuel N₂ fixation during daylight hours. In addition, the heterocysts retain the catabolic machinery necessary for aerobic consumption of carbohydrate supplied by vegetative cells. Hence,

by spatially separating photosynthesis from N₂ fixation, heterocystous cyanobacteria are able to actively fix N₂ during the daytime, and at night these organisms can continue to fix N₂ at a reduced rate through catabolism of photosynthetically fixed organic matter (Stal and Zehr, 2008). It is unclear whether this strategy for N₂ fixation might influence the establishment or maintenance of symbiotic interactions prevalent among oceanic heterocystous cyanobacteria and other photolithoautotrophs (e.g., diatoms).

Similar to heterocystous cyanobacteria, the non-heterocystous *Trichodesmium* also fixes N₂ during the day coincident with photosynthetic production of O₂. The mechanisms underlying the ability of *Trichodesmium* to fix N₂ at the same time when it is also actively producing O₂ through photolithoautotrophic growth is the subject of continuing debate. Both photosynthesis and N₂ fixation in *Trichodesmium* are regulated at the level of gene transcription through a tightly coordinated circadian rhythm; moreover, *Trichodesmium* appears to adjust its respiratory rate to control intracellular O₂ concentrations. Two different hypotheses have emerged to explain how *Trichodesmium* fixes N₂ during the day: (1) nitrogenase is spatially segregated into differentiated nonphotosynthetic cells similar to heterocysts, or (2) cells within *Trichodesmium* filaments cycle rapidly between N₂ fixation and photosynthesis, thereby temporally separating N₂ fixation and photosynthesis (Stal and Zehr, 2008). To date, it remains unclear which of these strategies is utilized in support of N₂ fixation.

Free-living, non-heterocystous photolithoautotrophs face additional challenges in protecting nitrogenase from O₂; this is particularly acute for unicellular N₂-fixing microorganisms where spatial isolation of N₂ fixation and photosynthesis is not possible. Various groups of N₂-fixing cyanobacteria have evolved the capacity to fix N₂ at night in the absence of photosynthetic O₂ production; marine N₂ fixers among the genera *Crocospaera*, *Cyanothece*, *Lyngbya*, and *Gloethece* all rely on temporal separation of N₂ fixation and photosynthesis. These organisms fuel the energetic demands of N₂ fixation via catabolism of photosynthetically fixed organic matter, a process that also consumes O₂.

Although photolithoautotrophic cyanobacteria have received considerable attention for their role in ocean N₂ fixation, recent discoveries suggest that some of the most abundant N₂-fixing cyanobacteria rely on a rudimentary photoorganoheterotrophic metabolism. Reconstruction of the group A cyanobacterial genome revealed that these organisms lack photosystem II but retain photosystem I, suggesting these organisms harvest sunlight for energy but do not evolve O₂ during photosynthesis (Zehr *et al.*, 2008). This discovery provides insight into the seemingly enigmatic observations that nitrogenase gene expression by group A peaks during the day (Church *et al.*, 2005), contrasting the strategy of temporal separation of N₂ fixation and photosynthesis observed in other unicellular cyanobacteria. The absence of photosystem II and the presence of photosystem I suggests N₂ fixation by group A is coupled to energy harvested through cyclic photophosphorylation without concomitant evolution of O₂. The source of reductant needed for reducing N₂ remains unknown but could include recycling of H₂ or catabolism of organic matter.

Non-cyanobacterial marine N₂ fixers include both aerobes and facultative and obligate anaerobes, and these organisms rely on diverse modes of acquiring energy and reductant such as chemoorganoheterotrophy, methanotrophy, and methanogenesis. In the open sea, various strains of chemoorganoheterotrophic γ -proteobacteria have been isolated that fix N₂ optimally under microaerobic or anaerobic conditions, including several strains belonging to the genera *Vibrio*, *Klebsiella*, and *Pseudomonas* (Zehr and Paerl, 2008). Although O₂ concentrations in the upper ocean are generally at or even slightly above saturation relative to the atmosphere, low O₂ niches for these organisms might exist within decomposing particles or within the guts of marine invertebrates. Other strategies employed by chemoheterotrophs for shielding nitrogenase from O₂ include building gas-diffusion barriers around the cell. Several groups of aerobic chemoheterotrophs, including *Azotobacter*, produce copious quantities of extracellular polysaccharides that, when combined with relatively high rates of respiration, appear to help minimize oxidative deactivation of nitrogenase (Fenchel *et al.*, 1998). Although little is known about the contribution of chemoorganoheterotrophs to oceanic N₂ fixation, the energetic demands of these organisms would likely require high rates of organic matter supply and thus likely limit their contributions to more-eutrophic but N-limited marine ecosystems (e.g., the Baltic Sea).

The Role of N₂ Fixation in Marine Ecosystems

Marine ecosystems are fundamental components of the global C cycle and N₂-fixing microorganisms factor prominently into the processes controlling ocean C inventories and fluxes. The biological C pump describes the collective set of processes that partly maintain the large vertical gradients observed in oceanic inorganic C concentrations. Net photosynthetic production of organic matter in the well-lit regions of the upper ocean consumes carbon dioxide (CO₂) and fuels the metabolic demands of the ocean's food web; however, due to gravitational settling of particles or convective mixing of dissolved organic matter, a fraction of this photosynthetically derived organic matter escapes immediate consumption in the upper ocean and is transported downward to the cold, unlit waters of the deep sea. During the downward transfer of this material, microorganisms actively decompose the sinking material, remineralizing organic matter back to inorganic constituents, including CO₂ (Figure 3).

The magnitude of C removal via the biological C pump depends in large part on the supply of growth requiring nutrients to the upper ocean (Eppley and Peterson, 1979). Although nutrient recycling in the upper ocean often supports a major fraction of biological productivity, the steady loss of material from the upper ocean via the biological pump needs to be supported by external nutrient subsidy. Dugdale and Goering (1967) formalized the terms "new" and "regenerated" production to describe the sources of nutrients (in their model based on N) supporting plankton production in the upper ocean. Regenerated production includes that fraction of production sustained by nutrient recycling in the euphotic zone, whereas new production describes plankton production

supported by nutrients supplied from outside the euphotic zone. If the upper ocean is assumed to be in steady state over some reasonable time and space scales, then input of new nutrients should be largely balanced by removal of these nutrient subsidies in the form of organic matter. Thus, in N-limited regions of the ocean, the supply of new N should be quantitatively related to organic matter export to the deep sea. Sources of new nutrients to the upper ocean include nitrate introduced largely by physical processes (turbulent mixing, advection, or upwelling), atmospheric deposition of N-containing compounds, and N₂ fixation. As a result, the supply of bioavailable N to the upper ocean via N₂ fixation forms a central component of the biological C pump.

Quantification of N₂ Fixation

Over the past several decades, considerable efforts have been made in quantifying the importance of N₂ fixation to marine ecosystems (Capone, 2001). Such efforts have included direct biological rate measurements or geochemical approaches to derive rates of N₂ fixation based on anomalous stoichiometric behaviors of inorganic C or nutrient pools, or stable isotopic signatures of planktonic N. Prior to routine use of the stable isotopes in biological oceanography, most biological efforts to quantify rates of N₂ fixation were based on the reduction of acetylene to ethylene. Nitrogenase demonstrates low substrate specificity to N₂, allowing the enzyme to reduce several other compounds that share molecular similarity to N₂, including acetylene. Hence, biological reduction of acetylene to ethylene has been used as a surrogate measurement for N₂ fixation. The method suffers from several uncertainties, perhaps most notably the selection of appropriate acetylene to N₂ conversion factors. The technique typically relies on gas chromatograph separation of ethylene followed by flame ionization or thermal conductivity detection of the gas; for natural samples where the abundance of N₂ fixers is relatively low, the methodology has historically demanded preconcentration of N₂-fixing microorganisms to increase the analytical sensitivity of this method. This preconcentration is often done by handpicking colonies or filaments of visible N₂-fixing cyanobacteria, with the resulting rate of acetylene reduction per colony or filament extrapolated based on enumeration of the abundances of the organisms in the environment. Although this approach provides useful information, in particular on physiological variability of ocean diazotrophs (Capone *et al.*, 1990), growing realization that many of the abundant and potentially important marine diazotrophs may not be easily distinguishable based on phenotypic characteristics (e.g., unicellular N₂ fixers) presents impediments to utilizing these derived rate measurements to obtain estimates of rates of N₂ fixation in the sea.

The development and application of ¹⁵N stable isotope-based approaches marked a major advance in quantifying rates of N₂ fixation. Tracing the assimilation of ¹⁵N-labeled N₂ gas into plankton biomass provides a direct means of determining rates of N₂ fixation; the sensitivity of the method has proven useful even in ecosystems where rates of N₂ fixation and abundances of N₂ fixers are low. However, the methodology also faces several limitations. In particular, dilution of the ¹⁵N₂ substrate by the large natural pool of dissolved N₂

Figure 3 Depiction of the role of new production in fueling the biological carbon pump. Vertical gradient in dissolved inorganic carbon (dashed line). New production and carbon export supported by NO_3^- and N_2 shown on left side of figure, whereas productivity fueled by regenerated nutrients (via recycling of NH_4^+) is depicted on right side of figure.

(> 600 μM) limits the sensitivity of the assay. Moreover, as commonly employed, the method measures the accumulation of ^{15}N into particulate material (cell biomass); and to the extent that release of ^{15}N labeled dissolved material (amino acids or NH_4^+) constitutes an important pathway for fixed N, the method would underestimate the rate of fixation. This is one potential advantage to using the acetylene reduction method: it may provide an estimate of N_2 fixation closer to gross rather than the net estimate likely obtained using the $^{15}\text{N}_2$ technique. Moreover, a recent study has uncovered a potentially serious flaw with the standard $^{15}\text{N}_2$ methodology: when $^{15}\text{N}_2$ is injected as a gas into seawater, the equilibration time for the $^{15}\text{N}_2$ with the seawater appears relatively slow, potentially resulting in underestimation of the rate of N_2 fixation (Mohr *et al.*, 2010). These authors modified the conventional method by dissolving the $^{15}\text{N}_2$ gas into the seawater prior to the incubation, then adding the equilibrated mixture to seawater samples; the resulting rates of fixation by *Crocospheera* were ~60% greater than rates estimated by the conventional “bubble injection” technique.

The just described methods have provided considerable insight into processes underlying variability in N_2 fixation in

different ecosystems and also suggest that the process can be highly variable in space and time. However, the value of extrapolating such measurements to obtain estimates of ecosystem- or global-scale rates of N_2 fixation remains unclear. Several geochemical approaches based on anomalous nutrient and inorganic C distributions provide additional constraints on basin- to global-scale N_2 fixation. Time-series measurements of inorganic C drawdown at the Bermuda Atlantic Time-series Study (BATS) in the Sargasso Sea revealed an intriguing seasonal pattern (Michaels *et al.*, 1994): wintertime convective mixing delivers nutrients and inorganic carbon to the euphotic zone; these nutrients are rapidly consumed in support of biological production and subsequent vertical export during the early- to mid-spring, resulting in net removal of inorganic C. However, throughout the warm summer and fall months when upper-ocean nutrient concentrations are at their annual minimum, inorganic C inventories continue to disappear, presumably a manifestation of an active biological C pump. Mixing, upwelling, and advection of nutrients do not appear sufficient to support new production during these periods (Michaels *et al.*, 1994). Similar observations emerged from the Hawaii Ocean Time-series (HOT) program in the

North Pacific (Karl *et al.*, 2002). These observations highlighted a potentially important role for N₂-fixing microorganisms in the open sea: by supplying a source of N to the upper ocean during the thermally stratified summer months, these organisms may provide nutrient subsidy to the oligotrophic oceans that ultimately fuels the biological C pump. Subsequent extrapolation of these observations to other regions of the ocean (based on satellite-derived sea surface temperatures) provided basin- to global-scale estimates of N₂ fixation–supported new production (Lee *et al.*, 2002).

Additional efforts to constrain basin-scale rates of N₂ fixation hinged on observed stoichiometric patterns in inorganic and organic nutrient pools. The congruence in elemental stoichiometries of deep ocean nutrient pools and planktonic

biomass has been known for many years. Globally, the molar ratio of N to phosphorus (P) found in seawater nutrient pools – namely, nitrate (NO₃[−]) and phosphate (PO₄^{3−}) – converges near 16 : 1, similar to the average N : P ratio of these elements found in marine plankton (Redfield *et al.*, 1958). However, examples of anomalous behaviors from this canonical ratio abound, and such examples have provided insight into the magnitude of N inputs and losses in ocean ecosystems. In the subtropical North Atlantic, inorganic N : P ratios of waters in the upper thermocline can exceed 50 : 1; whereas in the subtropical North Pacific, the N : P ratios of upper ocean and thermocline nutrient pools are nearly always < 1 : 1 (Figure 4). Two important N-cycle processes are known to effectively decouple the cycling of N and P in the sea: N₂

Figure 4 Processes contributing to vertical relationships in inorganic nutrient (NO₃[−] and PO₄^{3−}) N : P ratios. N : P ratios for the subtropical Pacific depicted by dashed orange line, whereas N : P ratio for subtropical Atlantic depicted by dashed green line; Redfield ratio (16N : 1P) shown with black dashed line. Low Fe deposition to the waters of subtropical North Pacific is hypothesized to limit N₂ fixation, which together with advection of denitrified waters to this region results in thermocline N : P ratios < Redfield ratio. In the subtropical Atlantic, enhanced Fe-enriched dust deposition is hypothesized to stimulate N₂ fixation and thereby consume P, resulting in thermocline N : P ratios of the remineralized nutrient pools > Redfield ratio.

fixation and denitrification. N₂ fixation provides a source of N to the ocean in a manner often decoupled from introduction of P, whereas denitrification removes fixed N independent from removal of P. Diazotrophs appear to demonstrate considerable flexibility in their biomass N : P ratios, thereby potentially introducing an N-rich source of organic matter that could fuel net remineralization in the deep ocean. Moreover, through direct release of dissolved N substrates (either NH₄⁺ or amino acids), N₂-fixing microorganisms have the potential to significantly alter seawater nutrient pools. Thus, in ecosystems where N₂ fixation constitutes an important supply term for fixed N, the remineralized inorganic nutrient pools and dissolved organic matter pools should reflect excess input of N relative to P. Such anomalous behavior in N : P nutrient stoichiometry has been used to constrain basin- to global-scale rates of N₂ fixation and denitrification (Michaels *et al.*, 1996; Gruber and Sarmiento, 1997; Deutsch *et al.*, 2007). Seawater nutrient N : P ratios indicate excess N input (presumably due to N₂ fixation) in the Atlantic, whereas net N loss (presumably due to denitrification) predominates in the Pacific. Note that these patterns do not necessarily imply that rates of N₂ fixation are greater in the Atlantic than the Pacific; high rates of N input by N₂ fixation in the Pacific could be obscured by greater denitrification occurring in this region (Gruber and Sarmiento, 1997).

There have been a number of challenges to the hypotheses that N₂ fixation supports the observed drawdown in inorganic C observed at HOT and BATS and that contemporaneous rates of N₂ fixation are sufficient to produce the anomalous N : P ratios observed in the thermocline of the North Atlantic. Isotopic analyses of the ¹⁵N signatures of NO₃⁻ and total N (largely dissolved organic N) suggest N₂ fixation may be only a small source (~2%) of new N input to the euphotic zone in these systems (Knapp *et al.*, 2005). These studies highlighted a number of considerations when constraining rates of N₂ fixation-based on patterns of anomalous nutrient stoichiometry. Foremost among these considerations is that we currently have poor estimates of the importance of processes other than N₂ fixation in contributing to anomalous nutrient N : P ratios; in particular, the potential importance of atmospheric deposition and non-Redfieldian nutrient remineralization. In addition, these studies point out that deviations in seawater nutrient N : P ratios from the canonical Redfield ratio may not provide insight into local-scale processes, but rather reflect a host of spatially integrated processes that ultimately result in N-enrichment of thermocline waters; such processes could include advection of water from regions that support high rates of N₂ fixation, or transport of water from regions where N is supplied to upper ocean via atmospheric deposition (Knapp *et al.*, 2005; Hansell *et al.*, 2007).

N₂ Fixation Fueled Linkages Among Nutrient Cycles

Marine N₂-fixing microorganisms appear well adapted to growth in warm, stratified, N-depleted habitats (Karl *et al.*, 2002). But if N₂-fixing microorganisms provide a source of fixed N to such ecosystems, why do so many regions of the tropical and subtropical ocean appear so tightly controlled by the supply and availability of N? What limits N supply by N₂

fixation in these ecosystems? Why aren't N₂-fixing microorganisms more abundant in these N-limited ecosystems? The persistent dearth of nutrients found in large regions of the open sea suggests that bioessential nutrients likely limit the capacity of these ecosystems to support new biomass. Plankton demand for nutrients has long been known to exceed supply in many regions of the sea, and given that low nutrient supply defines oligotrophic habitats, there is considerable interest in identifying how N₂-fixing microorganisms obtain nutrients needed for growth. Much of the focus has been directed toward understanding how N₂-fixing microorganisms meet their nutritional demands for P or Fe or vitamins. Over geological time scales the availability of Fe and P appear important regulators of ocean C sequestration via the biological C pump, in part through the role these elements play in controlling N₂ fixation (Falkowski, 1997). Both Fe and P are introduced to the oceans through weathering of rock and soils, with P delivery to the oceans mostly via riverine runoff and Fe supplied by wind-borne deposition of dust. Both Fe and P are essential components of biomass: P is central to synthesis of nucleotides and lipids, whereas Fe is central to numerous protein systems including those required for electron transport, photosynthesis, and nutrient assimilation.

Understanding how the introduction of bioavailable N to the planktonic food web by the activities of N₂-fixing microorganisms impacts the availability and turnover of other nutrient elements in the ocean continues to be a subject of intense study. Such new N input should increase planktonic demands for P, and in fact examples of secular-scale changes in P inventories have been attributed to changes in N₂ fixation (Karl *et al.*, 1997). The eventual drawdown of P due to N₂ fixation establishes various feedbacks, including imposing P stress or even limitation on diazotroph growth. N₂-fixing microorganisms possess high affinity P uptake systems that permit them to harvest very low concentrations of PO₄³⁻. Nonetheless, kinetic studies on *Trichodesmium* suggest both growth and P-uptake limitation can be limited at PO₄³⁻ concentrations < 0.2 μM (Fu *et al.*, 2005), which occurs in most of the regions of the sea where these organisms thrive. To cope with such P-stress, various groups of marine diazotrophs appear to acquire P through utilization of organic compounds, including phosphomonoesters or polyphosphates (Karl and Björkman, 2002). Although *Crocospaera* and *Trichodesmium* encode alkaline phosphatases and polyphosphatases for hydrolyzing phosphate esters and polyphosphates, respectively, *Trichodesmium* appears to have further diversified its mode of acquiring P through utilization of phosphonate compounds. Phosphonates are a unique subset of C–P bonded organic substrates that comprise a relatively large fraction of organic P found in seawater (Dyrhman *et al.*, 2006). Intriguingly, laboratory and field-based studies indicate that diazotroph growth on selected alkylphosphonates (methyl- and ethylphosphonate) results in production of the corresponding alkanes (e.g., methane and ethane) thereby linking the P scavenging metabolism of these organisms to production of climate-reactive gases (Karl *et al.*, 2008). Marine N₂ fixers also demonstrate considerable flexibility in their cellular P quotas, with cellular N : P ratios ranging from 16 : 1 to 90 : 1 (White *et al.*, 2006). Part of this flexibility likely derives from

the ability to limit their cellular demand for P through substitution of sulfur in membrane lipids (Van Mooy *et al.*, 2009) or through reduction in P-rich ribosomes (Arrigo, 2005). These adaptations to low P conditions further highlight the complexity of factors that shape diazotroph biodiversity in the sea.

The large Fe-demands of nitrogenase (enzyme contains up to 50 mol Fe per mole of the enzyme complex) appears to place relatively large Fe requirements on N₂-fixing microorganisms. *Crocospaera* appears to partly deal with this high demand for Fe through intense intracellular Fe recycling (Saito *et al.*, 2011); however, net diazotroph growth in the oceans still demands a supply of Fe. Such elevated Fe requirements have focused attention on whether low delivery of Fe to the oceans might limit contemporary rates of N₂ fixation. Stimulation of N₂ fixation through eolian Fe deposition has been proposed as a mechanism underlying basin-scale differences in NO₃⁻ : PO₄³⁻ ratios observed between the Atlantic and Pacific (Figure 4); whereas NO₃⁻ : PO₄³⁻ ratios in the main thermocline of the Atlantic exceed the Redfield ratio (16 : 1), in the Pacific ratios of these nutrient pools are consistently below this canonical ratio (Figure 4). Delivery of Fe-rich Saharan dust to the central Atlantic has been hypothesized to support euphotic zone N₂ fixation (Michaels *et al.*, 1996; Moore *et al.*, 2006), a process that would fuel formation of N-enriched organic matter that ultimately results in N-enriched remineralized inorganic nutrients below the euphotic zone. Several direct field tests of this hypothesis indicated both Fe and P can limit N₂ fixation in these waters, consistent with the view that Fe delivery controls N₂ fixation which in turn regulates P inventories (Mills *et al.*, 2004; Sañudo-Wilhelmy *et al.*, 2001). In contrast, eolian Fe input to the relatively remote waters of the Pacific appears lower and possibly limits N₂ fixation, thereby creating the relative surplus in PO₄³⁻ observed throughout the euphotic zone waters of the Pacific (Wu *et al.*, 2000; Cavender-Bares *et al.*, 2001).

Several recent intriguing developments in the study of factors controlling rates of N₂ fixation in the global ocean have explored coupling between different processes in the N cycle and how these processes influence the relative distributions of nutrient elements necessary to support diazotrophs. In particular, ocean models hint that physical transport of denitrified waters with low NO₃⁻ : PO₄³⁻ ratios could effectively couple the processes of N₂ fixation and denitrification at the global scale (Deutsch *et al.*, 2007). Denitrification removes fixed N and leaves residual P relative to the Redfield ratio. The process occurs in low-O₂ waters, including regions in the Arabian Sea and along the eastern boundaries of the Pacific and Atlantic Oceans. Reintroduction of these relatively P-enriched waters to the euphotic zone has been hypothesized to promote N₂ fixation. Together, these hypothesized interactions between N₂ fixers and Fe supply or coupling with denitrification reinforce the key role of N₂-fixing microorganisms in linking elemental cycles in the sea and highlight possible climate-sensitive feedbacks regulating the ocean's N cycle. Future perturbations to Earth's climate, either via the hydrological cycle or warming, could alter the magnitude and spatial distribution of dust inputs and denitrification, impacting N₂ fixation, nutrient distributions, and the biological C pump.

Patterns and Progress in Diazotroph Ecology

A hallmark of N₂-fixing microorganisms is their ability to modify their environment through introduction of fixed N, thereby provoking a suite of subsequent changes in overall ecosystem dynamics. As previously described, the inevitable drawdown of other bioessential nutrient pools (including P and Fe) modifies the stoichiometry of seawater nutrient pools that the diazotrophs depend on for growth. Through their growth, N₂-fixing microorganisms appear to establish self-imposed feedbacks that ultimately influence their competitive success and shape ecosystem biodiversity. There has been considerable effort directed toward defining emergent patterns in the distributions and activities of marine N₂ fixers, and this has provided a wealth of information on spatial and temporal dynamics underlying diazotroph ecology. It has become increasingly clear that despite apparent functional redundancy among members of the marine diazotroph guild, the genetic and metabolic diversity of N₂-fixing microorganisms has direct bearing on ocean ecology and biogeochemical cycling. In the following sections, we highlight a small subset of intriguing findings that point to the importance of oceanographic processes in structuring diazotroph diversity and the role of this diversity in driving biogeochemical cycles.

Spatiotemporal Variability

With the recognition that N₂ fixers are keystone functional members of the planktonic food web, interest in defining the biogeography of diazotrophs, with an eye to identifying factors that shape the resulting patterns, has increased. Although the generalized distributions of microscopically identifiable N₂-fixing microorganisms has been known for many years, the use of molecular-based approaches has provided new tools to examine the distributions and activities of different groups of N₂ fixers (including many only known based on gene sequences) and in some cases expanded the geographical boundaries of habitats known to support N₂-fixing microorganisms. Although these studies have confirmed that N₂-fixing microorganisms appear best suited to the warm, nutrient-poor regions of open sea, they have also highlighted several important biogeographical distinctions in the types of organisms that predominate in these regions. For example, the uncultivated unicellular group A appears better adapted to lower temperatures and greater nutrient concentrations than other marine N₂ fixers, extending its geographic range in the oceans to include the extremes of the subtropical gyres (Moisander *et al.*, 2010; Sohm *et al.*, 2011). Although we recognize that abundances and activities of N₂-fixing microorganisms are highly variable in space and time, despite years of research, in most cases the processes underlying this variability remain unknown. Moreover, most studies on distributions and diversity of marine N₂-fixing microorganisms have focused on cyanobacteria and our understanding of spatial and temporal variability associated with non-cyanobacterial N₂ fixers remains weak. Those few studies that have explored distributions and diversity of these non-cyanobacterial N₂ fixers suggest such diazotrophs may exhibit a larger geographic range than the cyanobacteria (Farnelid *et al.*, 2011).

At the basin scale, several prominent biogeographical features emerge from studies on marine diazotroph diversity and distributions: (1) *Trichodesmium* appears to be a dominant N₂ fixer in the tropical and subtropical waters of the Atlantic Ocean; (2) unicellular N₂ fixers often dominate diazotroph abundances in the subtropical Pacific; (3) despite the presence of diverse N₂-fixing microorganisms in the Mediterranean Sea, the P-depleted waters of this ecosystem appear to support very low rates of N₂ fixation; and (4) diazotroph dynamics in the southern hemisphere remain grossly undersampled, limiting our understanding of N₂ fixation in large areas of the Indian Ocean, and both the South Pacific and Atlantic Oceans. Although it is tantalizing to infer that temperature is the primary selective force on these larger-scale biogeographic patterns, changes in temperature often coincide with alterations in physical forcing of the upper ocean, which can have indirect consequences on light availability and nutrient supply. Although both the physiology and distributions of various N₂-fixing microorganisms demonstrate temperature dependent patterns, diazotroph abundances in the warm, nutrient-enriched waters of the equatorial Pacific are low (Figure 5), suggesting temperature is not the primary controller of N₂ fixers in this ecosystem. Such meridional patterns could stem from a variety of processes, including limitation of N₂ fixers by low Fe supply, or the inability of diazotrophs to effectively

compete for growth limiting nutrients in a habitat where NO₃⁻ is supplied to the upper ocean via physical processes (in this case upwelling). Studies with laboratory isolates of *Trichodesmium* and *Crocospaera* indicate that N₂ fixation is repressed in the presence of NH₄⁺ at concentrations above ~0.2 μM, but that rates of N₂ fixation by these organisms can be less sensitive to changes in NO₃⁻ concentrations (Ohki *et al.*, 1991; Dekaezemaeker and Bonnet, 2011). However, NO₃⁻ supply to the N-starved upper ocean would almost certainly instill intense competition for growth limiting nutrients among naturally occurring plankton assemblages. N₂ fixers generally appear to grow more slowly than non-diazotrophic phytoplankton, presumably as a result of the relatively high energy demands imposed by N₂ fixation, and this could limit their ability to effectively compete for resources in environments where NO₃⁻ supply is not limiting.

Our expanding knowledge of broad-scale patterns related to diazotroph population structure has proven fruitful for formulating new hypotheses on the ecological and physiological dynamics underlying these patterns (LaRoche and Breitbarth, 2005). However, exploration of notable exceptions to these patterns has also proved important to developing mechanistic understanding into processes controlling diazotroph diversity in the sea. The oceans are temporally and spatially heterogeneous habitats and this heterogeneity factors

Figure 5 Sea-viewing wide field-of-view sensor (SeaWiFS) satellite-composite image depicting distributions of surface ocean chlorophyll in the Pacific Ocean, with cruise tracks from five research expeditions shown (a). Panels (b) and (c) depict meridional distributions of near-surface ocean nitrate (NO₃⁻), temperature, and cyanobacterial *nifH* gene abundances obtained from the five cruises shown in (a). Dashed line (c) indicates approximate detection limit of quantitative PCR-based *nifH* gene determinations. Heterocysts includes sum of *Richelia* and *Calothrix* phenotypes.

prominently into shaping diazotroph dynamics. Oceanic fronts, riverine plumes, and mesoscale eddies all superimpose physical and biogeochemical variability onto otherwise relatively quiescent regions of the sea, and such features appear to influence diazotroph dynamics. For example, the diazotroph habitat expands and contracts with meridional changes in the major frontal features that define the extremes of the subtropical gyres (Church *et al.*, 2008). In the North Pacific, interannual- to seasonal-scale changes in the strength of westerly and trade wind forcing alters the latitudinal positions of fronts along both the northern and southern boundaries of the oligotrophic subtropical gyre, expanding or contracting the areal extent of this habitat by $> 10^6$ km². In addition, riverine input to marginal zones along the tropical and subtropical oceans is an important factor in control on N₂ fixer dynamics in these ecosystems. Studies in both the Amazon and Mekong river plumes indicate that riverine discharge of terrestrial material establishes a spatially extensive succession of planktonic organisms that includes a prominent role for N₂ fixers (Foster *et al.*, 2007; Subramaniam *et al.*, 2008; Voss *et al.*, 2006). The silica, Fe, and P enriched waters associated with such river plumes appears to promote the growth of N₂ fixers, specifically diatom-associated heterocystous cyanobacteria. Hence, time-varying changes in the intensity and spatial dynamics of the plume discharge directly contribute to variability in diazotroph dynamics in such regions.

Mesoscale eddies have long been recognized as important controls on physical and biogeochemical variability in the oceans. Eddies are ubiquitous features in the sea; these isolated vortices are typically 10–100 s of kilometers in diameter, and most persist for weeks to months. Eddies develop due to instabilities in flow along frontal boundaries or through wind-driven forcing at topographic features. Depending on the direction of their rotation, eddies alter nutrient availability in the upper ocean waters. Most of the attention on how mesoscale eddies impact marine plankton has focused on cyclonic eddies, whose rotation results in uplift of nutrient-enriched waters into the euphotic zone. However in both the Atlantic and Pacific, the activities and abundances of N₂-fixing organisms appear enhanced by downwelling anticyclonic eddies; the growth of *Trichodesmium*, *Crocospaera*, and diatom-associated heterocystous N₂ fixers appear stimulated by such physical forcing (Davis and McGillicuddy, 2006; Church *et al.*, 2009). Nevertheless, the mechanisms that promote N₂ fixation by specific organisms associated with these features remain unknown.

We currently have considerably more information on spatial variability in N₂-fixing microorganisms than we do on time-varying changes in these organisms. However, deconvolving spatial and temporal variability in a dynamic fluid environment is often difficult. Much of our understanding of temporal variability in marine diazotrophs derives from time series sampling at a few locations in the world's oceans. Several studies based at HOT and BATS examined time-variability in the dynamics of N₂-fixing microorganisms, specifically *Trichodesmium* and heterocystous cyanobacteria (Letelier and Karl, 1996; Orcutt *et al.*, 2001). Among other findings, these studies highlighted episodic blooms as important features of the ecology and biogeochemistry of marine N₂ fixers. Although diazotrophs are generally found in low abundances

in the open sea, *Trichodesmium*, *Calothrix*, and *Richelia* are notable for occasionally forming large blooms and possibly dominating plankton biomass during these events. In some cases, these blooms are often large enough in magnitude as to be detectable by Earth-orbiting satellites (Westberry and Siegel, 2006; White *et al.*, 2007). Most often these blooms are observed during the summer months, when the upper ocean is stratified, and nutrient supply to the upper ocean is presumably at its annual minimum. The net accumulation of biomass during such bloom events implies that on some time scale, processes controlling the growth and loss of these organisms have become decoupled. The expansion of biomass during blooms events could derive from non-steady state behavior in either bottom-up or top-down controls on diazotroph populations. Although top-down processes are undoubtedly important controls on population ecology, in many regions of the open sea limited nutrient supply would appear to leave little room for expansion of diazotroph population sizes. To date it remains unclear what processes result in the initiation of net growth of N₂-fixing microorganisms or how those processes change to eventually terminate these blooms. However, the impact of these blooms on ocean biogeochemistry is apparent. At HOT, a recurrent summertime increase in the flux of organic carbon to the deep sea accounts for $> 30\%$ of the annual carbon export in this ecosystem (Dore *et al.*, 2008). Microscopic analyses of sediment trap samples from this site revealed that this temporally focused pulse of material to the deep sea is driven by sinking diatoms, many of which contain endosymbiotic *Richelia* (Scharek *et al.*, 1999). Although the processes that control this sedimentation phenomenon remain unknown, the observations highlight an important role for time-varying changes in diazotroph population structure on ocean carbon sequestration.

Time series sampling of *nifH* gene abundances and upper ocean N₂ fixation (based on assimilation of ¹⁵N₂) at HOT has provided insight into seasonal to event scale fluctuations in the diazotroph assemblage dynamics (Figure 6). During most of the year, *nifH* gene abundances are dominated by unicellular cyanobacteria, specifically group A. However, as the upper ocean warms and becomes more stratified between the late spring and fall, filamentous N₂ fixers (including *Trichodesmium*, *Richelia*, and *Calothrix*) become increasingly abundant. These seasonal-scale changes in diazotroph community structure appear to directly influence rates of N₂ fixation. More than 70% of the annual N₂ fixation appears controlled by microorganisms < 10 μ m in diameter (presumably reflecting the activities of group A and *Crocospaera*); however, during those months when filamentous organisms become more dominant, rates of N₂ fixation by larger (> 10 μ m in diameter) organisms increase. Thus, larger filamentous organisms appear best adapted to periods when upper ocean nutrient supply is low, but energy is plentiful, whereas unicellular microorganisms appear to flourish during the cooler, more nutrient-enriched winter and spring months. These seasonal-scale shifts in the size structure of marine diazotrophs appear contradictory to conceptual models which predict larger celled plankton flourish under periods of elevated nutrient supply, whereas picoplankton appear better suited to periods when turbulence is low and nutrient supply limiting.

Figure 6 Monthly determinations of depth-integrated (0–100 m) *nifH* gene inventories (a) and rates of N₂ fixation (b) by two size classes (<10 μm and >10 μm) of microorganisms in the subtropical North Pacific Ocean. Filamentous *nifH* groups includes the sum of *Trichodesmium*, *Richelia*, and *Calothrix*; whereas unicellular phylotypes include sum of *Crocospaera* and group A phylotypes.

Diazotrophy in the Changing Sea

The organization of microbial assemblages underlies many of the emergent properties of marine ecosystem functions, including the pathways and efficiency through which energy gets dispersed and material gets retained within the food web. Fluctuations in environmental forcing – that is, nutrient supply, solar energy input, redox conditions – all directly influence the organization and structure of planktonic communities. Hence, understanding the sensitivities and resilience of contemporary ecosystem functions to changes in microbial diversity is central to our predictive knowledge on how these systems may change in the future. There are clear examples of progressive changes occurring in ocean habitats, many

attributable to anthropogenic activities, but our knowledge of how such changes are shaping plankton biodiversity, and more specifically diazotroph diversity, remain largely rudimentary. Both measurements and models hint that climate-driven changes may favor expansion of warm, low nutrient marine ecosystems that comprise key habitats for N₂-fixing microorganisms, likely increasing the ecological and biogeochemical footprint of diazotrophy in the sea. However, such expanded habitats could differ significantly from the oligotrophic gyres we recognize in contemporary oceans, with lower pH, elevated temperatures, and dampened seasonality in nutrient entrainment. If the apparent genomic conservation demonstrated by members of *Trichodesmium* and *Crocospaera* (Zehr *et al.*, 2007) turns out to be a distinguishing feature

among other groups of marine diazotrophs, this characteristic may reduce the genetic flexibility available to these organisms and make these populations potentially less resilient to future changes in environmental selective pressures.

Some of the most robust examples of progressive ocean change are found in decadal-scale records of the seawater carbonate system. Ocean CO₂ inventories are increasing in step with atmospheric CO₂, driving concomitant decreases in seawater pH. These changes in the seawater carbonate system influence life in the sea in a myriad of ways, ranging from direct physiological changes to alteration in the speciation of bioessential metals, and thus are likely to exert increasingly important selective pressures on marine plankton, including the diazotrophs. Laboratory studies have documented how N₂-fixing microorganisms acclimate to abrupt experimental manipulations in key habitat properties (e.g., light, nutrients, temperature, CO₂). Such studies have revealed sensitivities in N₂ fixers to changes in CO₂; however, the responses by different organisms can be varied and complex. Growth and N₂ fixation by different strains of *Trichodesmium* and *Crocospaera* increase under elevated CO₂ conditions (Hutchins *et al.*, 2009; Levitan *et al.*, 2007), whereas other diazotrophs such as the bloom-forming heterocystous cyanobacterium *Nodularia* demonstrate a negative response to increasing CO₂ (Czerny *et al.*, 2009).

Designing and conducting experiments that adequately simulate adaptive responses by the microorganisms to slow and progressive ecosystem change remains challenging. It is currently unclear to what extent information obtained from short-term acclimation experiments will be useful in helping to predict future changes to ocean diazotrophs. Although many of the projected changes to the ocean habitat would appear favorable to growth of specific N₂-fixing microorganisms, such changes could also trigger new ecosystem stress points that feedback onto the N₂ fixers. For example, possible stimulation of diazotroph growth by increased CO₂ availability might further stress demand for limiting nutrients in the open sea, potentially offsetting any physiological benefit associated with increased CO₂ availability. We currently have limited information on the physiological tolerances of naturally occurring ocean diazotrophs or how simultaneous changes in multiple climate-sensitive factors might interact to influence the resulting physiologies of these organisms.

Conclusions

Diazotrophs have long been recognized as functionally important members of the ocean plankton. Increasing interest in the role these organisms play in ocean C cycling has pushed understanding those processes controlling their growth, rates of N₂ fixation, distributions, diversity, and abundances to the forefront of biological oceanography. Despite often comprising a low proportion of plankton biomass, N₂-fixing organisms are metabolically diverse and thus spatiotemporal shifts in their population structure can impart distinct biogeochemical signatures on marine ecosystems. Moreover, these diverse groups of microorganisms appear sensitive to environmental forcing, suggesting these organisms could be early responders to future changes in the sea. There are many unanswered questions regarding their ecology and

biogeochemistry, but it is clear that these organisms provide several unique ecosystem services, making them essential components of contemporary marine systems. Several key themes related to marine N₂-fixing microorganisms that we have sought to emphasize here include:

1. Marine diazotrophs exhibit a wide range of metabolic diversity, including organisms that are photolithoautotrophs, photoorganoheterotrophs, and chemoorganoheterotrophs, and those both obligate and facultative aerobes and anaerobes.
2. Introduction of fixed N to the open sea by N₂ fixation has numerous consequences on ecosystem dynamics, including regulating material export to the deep sea, altering the elemental stoichiometry of ocean nutrient pools, and influencing production of reduced gases.
3. Input of new N via N₂ fixation has required reassessment of the processes and mechanisms that supply other bioessential nutrients (e.g., P and Fe) to ocean ecosystems.
4. Marine diazotrophs demonstrate complex and diverse ecological interactions, including prominent roles for symbiotic interactions, many of which remain poorly understood.
5. Our knowledge of the biogeochemical importance and ecological dynamics of non-cyanobacterial marine diazotrophs remains woefully scant.
6. The diversity and activities of marine diazotrophs appear susceptible to projected future changes to the ocean's climate and C cycle.

Glossary

Community The most practical definition is a set of species that interact at a given location.

Connectivity web This type of food web illustrates only feeding links without reference to strength of interaction or energy flow.

Detrital shunts Energy and nutrients from the saprovores web re-enter the plant herbivore predator food web when detritivores are eaten by predators that also eat plants, herbivores, or other predators.

Donor control Consumer population growth is affected by their resources but consumers do not affect the renewal rate of these resources and hence cannot depress their resources.

Ecosystem Set of one or more communities and their abiotic environment.

Energetic web This type of food web quantifies the amount of energy (or material) that flows across links joining species.

Food chain Representation of the links between consumers and their resources, for example, nutrients → plant → herbivore → carnivore. In these representations, energy or material flows up the chain in a linear fashion. In addition, a food chain can be a linear set of species within a food web.

Food or biomass pyramid Graphic representation of the energy or biomass relationships of a community, in which

the total amount of biomass, or total amount of energy available, at each successive trophic level is proportional to the width of the pyramid at the appropriate height.

Food web Representation of feeding relationships in a community that includes all the links revealed by dietary analysis.

Functional or interaction web This type of food web quantifies the strength of interaction between species linked using data from manipulative experiments.

Recipient control Consumers substantially depress populations of their resources.

Spatial subsidies Input from other habitats of organic carbon, nutrients, and prey or the movement of consumers. These resources can influence greatly the energy, carbon, and nutrient budget of recipient habitats. In general, nutrient inputs (nitrogen, phosphorus, and trace elements) increase primary productivity; detrital and prey inputs produce numerical responses in their consumers.

Trophic level An abstract classification to describe subsets of species that acquire energetic resources in a similar way on a subset of species (e.g., top carnivores feed on primary carnivores which feed on herbivores which feed on primary producers). In natural systems, most species do not feed strictly on the "trophic level" below them, making the trophic level concept a difficult term to assign operationally to species.

Introduction

Food webs occupy a central position in community ecology. Charles Darwin introduced the concept of an entangled bank in which he envisioned many kinds of species interdependent on each other in a complex manner governed by "laws acting around us." In the simplest context, food webs incorporate the two factors that, a priori, one would consider most fundamental to the success of any one species: resources and enemies. All species must acquire resources (food or nutrients) and suffer energy losses or mortality from predators (Figure 1). The abundance and success of any species is thus a product of these feeding interactions. This inclusion of such "bottom-up" (productivity and resources) with "top-down" (consumption) factors largely determines the distribution and abundance of almost every species on the planet. In particular, freshwater ecologists have enjoyed notable success by concurrently studying the interaction between these variable factors on the regulation of plant and animal abundance and thus the structure of freshwater communities. This research shows the

rich dynamical outcomes that can occur when predation and productivity vary and interact within a food web (Figure 2).

Many important advances have arisen from analyses that concurrently incorporate more than one interaction in a food web: keystone predation and herbivory, the intermediate predation and disturbance hypotheses, the size-efficiency hypothesis, trophic cascades, intraguild predation, apparent competition, and the recognition of the importance of indirect effects. The outcome of virtually all interactions within a community can be modified, directly and indirectly, by other members of the food web. This insight penetrates to all areas of community ecology. For example, the results of experiments must be interpreted carefully for at least two reasons. First,

Figure 1 Food chain.

[†]Deceased.

Figure 2 Food web.

indirect effects, moderated by other species in the web, may exert large and sometimes contradictory effects to the direct effects of the manipulation. Thus, under some food web configurations, removal of a predator may directly increase the level of its prey or may actually cause the prey to decrease because of indirect interactions. Second, changes in species dynamics putatively caused by one factor may actually be a product of a second process.

Types of Food Webs

Food web research has grown at a tremendous rate and taken a diversity of forms. Not surprisingly, ecologists have diverged in their methods, emphases, and approaches. Nevertheless, trophic relationships in communities can be delineated in three basic ways. Paine (1980) and Polis (1991) distinguished three types of food web that evolved from the ecological studies (Figure 3). The first is the classic food web, a schematic description of connectivity specifying feeding links.

Such connectivity webs simply demonstrate feeding relationships. Examples of these are the early food webs of Forbes and Summerhayes and Elton (Figure 3). The second web type is also descriptive, quantifying the flow of energy and matter through the community. These energetic webs quantify the flow of energy (or materials) between trophically connected species. Examples of this type of food web include intertidal communities in Torch Bay, Alaska, and Cape Flattery, Washington (Paine, 1980). The third type use experiments to dissect communities to identify strong links and dynamically important species. Such interaction of functional webs demonstrates the most important connections in an ecosystem (Figure 3). These food webs depict the importance of species in maintaining the integrity and stability of a community as reflected in its influence on the growth rates of other species. They require experimental manipulations of the community (e.g., by removal or addition of particular species). In the following sections, we discuss the strengths and weaknesses of each approach. Of the three, only the last two have contributed substantially to our understanding of natural systems.

Figure 3 Three conceptually and historically different approaches to depicting trophic relationships, illustrated for the same set of species. The connectedness web (a) is based on observation, the energy flow web (b) on some measurement and literature values, and the functional web (c) on controlled manipulation. Reproduced from Blackwell Scientific Publications.

Connectivity Webs

Connectivity webs are representations of “who eats whom” without inference to the strength or type of interaction and energy flow (Figure 3). Early food webs were constructed for essentially two reasons: (1) to depict the interconnectivity of natural systems and (2) to examine issues of “the balance of nature,” i.e., to analyze how harmony is maintained through complex predatory and competitive interactions within communities (Forbes, 1887). Such an approach was applied to agricultural systems to examine pests and possible food web manipulations to control pests. As early as the 1880s, beetles were introduced into the US to control agricultural pests. Such control then benefited crop plants *via* an indirect interaction (predator pest prey crop) (following the success of *Vedalia*, a coccinellid beetle, in controlling cottony-cushion scale in California in 1888, about 50 more coccinellids were introduced in the 1890s).

The knowledge required to construct connectivity webs is straightforward: An approximate, qualitative knowledge of who eats whom is all that is necessary to produce a simple food web, whereas experimental manipulations or quantitative measurements are necessary to construct webs of interaction or energy flow. Consequently, connectivity webs most frequently represent trophic interactions in communities and have received the most attention. Hundreds of such webs slowly accumulated over a century. They were useful to illustrate, in a totally nonquantitative manner, the feeding interactions within a specific community. Different scientists

constructed webs of different diversity, complexity, and resolution, depending on their knowledge of the system and bias or understanding of particular groups. For example, some may emphasize birds and lump all insects as one group. Others will divide the insects into scores of groups and represent one or two bird species.

In the 1970s and 1980s, many theoretical and statistical studies were performed on connectivity webs cataloged from the literature to determine similarities and natural patterns among them. Empirical generalizations were abstracted from data of published connectivity webs. These “natural patterns” largely agreed with predictions made by early food web models. These models showed that food webs were constrained to be quite simple: Each species ate few species and had few predators; the total length of the number of links in a typical food chain was short, usually two or three; omnivory was very rare; and there were a few other patterns. Early modelers argued that the congruence of patterns from the cataloged webs validated the predictions of their models. They thus claimed that their Lotka–Volterra models were heuristic and represented processes that structure real communities. For example, the addition of omnivory to model food webs causes webs to be unstable dynamically and exhibit relative low persistence (time before species are lost). Thus, these models make the prediction that omnivory should be relatively rare in those webs which persist in nature. Comparison of omnivory in cataloged webs relative to its frequency based on chance, shows that omnivory is statistically rare in real webs, as predicted by models. The same general approach was used to

validate other predictions of model webs, for example, short chain lengths.

Thus, modelers soon “explained” these empirically derived patterns. Although these studies, and the connectivity approach, make good food web diagrams, they are flawed to such a great degree that today such analyses are viewed as providing little understanding of natural communities. There are many reasons why this is so, of which only a few are mentioned here.

1. Most species are vastly under-represented in food webs or lumped in taxonomic or functional groups. Most communities have hundreds to thousands of species, but these webs would represent <10–30 species on average. As a consequence, most connectivity webs have severe problems with “lumping” species and taxonomic biases. Some trophic levels are distinguished by species (e.g., birds or fish), whereas other groups suffer a high degree of aggregation, for example, all species of insect or annual plants are represented as one super-species – “insects” or “plants” (Figure 4).
2. Most species are highly omnivorous, feeding on many resources and prey so that each has a distinct trophic history and are often at different trophic levels. Because diet is very difficult to delineate, most connectivity webs greatly under-represent the true nature of omnivory. This poses several fundamental problems.
3. Connectivity webs typically only offer a static view of the world and webs are usually idealized representations that show all linkages that occur over large spatial and temporal scales. Therefore much of the important variability and changes due to local environmental conditions are lost. However, studies that compare changes in connectivity over time and space and across environmental gradients (such as those by Mary Power and her group on the Eel River) can provide important insight into community structure and dynamics. One can view connectivity webs as a first step in examining the interactions in communities (i.e., performing “natural history” studies), to be followed by quantification of the fluxes of energy and nutrients (as in energetic webs).

Energetic Webs

Starting with the classic studies of Elton, Summerhayes, and Lindeman, food web studies turned toward quantifying flows of energy and nutrients in ecosystems and the biological processes that regulate these flows. This approach is an alternative to connectivity webs to describe trophic connectedness within communities. This “process-functional” approach explicitly incorporates producers, consumers, detritus, abiotic factors, flow out of a system, and the biogeochemical recycling of nutrients. It views food webs as dynamic systems in time and space. Such an approach necessitated analyzing energy and material fluxes in order to understand the behavior of ecosystems. Thus, a typical analysis would quantify the amount of energy or matter as it travels along different pathways (e.g., plants → consumers → detritus → decomposers → soil). For example, the tracking of energy and dichlorodiphenyltrichloroethane (DDT) through a food web in a Long Island estuary enabled researchers to study bioaccumulation effects on top predators.

The use of energetic webs has provided a rich understanding of the natural world and allowed us to understand much about ecosystems. Several important processes are included in energetic webs. First, they quantify energy and material pathways and key species or processes that facilitate or impede such flows. Second, they include an explicit recognition of the great importance of detritus, a subject virtually ignored in connectivity webs. (10 to >90% of all primary productivity from different habitats immediately becomes “dead” organic detritus rather than being eaten by herbivores). Third, this approach recognized a great amount of energy, nutrients, and prey that originated outside the focal habitat, which is a key insight to understand natural communities. Thus, energetic webs show how ecosystems function and which species dominate biomass and energy.

Beginning with Lindeman, researchers began to examine the efficiency of transfer from prey species to predator species. It was found that energy transfer is generally inefficient with only about 5–15% of the energy of prey species being converted to energy of predators. Yodzis (1989) used this information to suggest that the length of food chains within a

Figure 4 Food web showing aggregation within some trophic levels but not others. (a) The dynamics of omnivory; (b) spatial subsidy; (c) detrital shunts.

community would be set by the amount of energy entering into the base of the chain. This argument was in opposition to Pimm and Lawton's suggestion that food chain length is set by the resilience of the chain. By resilience, Pimm and Lawton, using Lotka-Volterra models, meant the estimated time for model food chains to recover from some disturbance. They argued that frequent disturbances (relative to growth rates of species) would result in shorter food chain lengths. Furthermore, early studies examining the influence of primary productivity (thus, the amount of energy entering a food chain) did not support the hypothesis that food chain length was governed by energy transfer efficiency. However, recent re-examinations of Pimm and Lawton's work suggest that two factors influenced their results – density-dependent regulation of the basal trophic level and food chain structure (the lack of omnivory in their models). Moreover, recent studies of the role of energy efficiency have found that decreases in productivity result in shorter maximum food chains. Thus, the relative role of resilience versus energy transfer in regulating the length of food chains is still debated.

One outcome of the argument for the role of energy transfer as the main governing factor of food chain length is a body of work that examines differences in energy efficiency among organisms. For example, carnivores are found to have greater efficiency than herbivores. Additionally, invertebrate ectotherms have greater efficiencies than vertebrate ectotherms, which in turn are more efficient than endotherms. Yodzis and Innes used this information (and relative body sizes) to parameterize nonlinear predator-prey models.

In summary, the analysis of energy and matter flow is necessary and central to understanding the dynamics of populations and communities. The success of a population is always strongly related to the energy and biomass available to it. Consequently, it is difficult or impossible to understand the dynamics and structure of food webs and interacting populations without incorporating energy flow from below. However, this energetic approach per se, although necessary, is not sufficient by itself to understand the dynamics of communities because energy flow and biomass production are functions of interactions among populations within the food web. The transfer of energy and matter becomes complicated as they pass through many consumers that populate community food webs. For example, increasing the amount of nutrients to plants may increase the biomass of each consumer in the web or may just increase the biomass of a subset of consumers (e.g., only the plants, plants and herbivores, or only the herbivores), depending on the relationship between consumers and their resources. Because of these considerations, pathways must be placed in the context of "functional" food webs to understand the dynamics of energy and material transfer.

Functional or Interaction Webs

Functional or interaction webs use experiments to determine the dynamics within a community. Starting with Connell and Paine, empiricists began to use experiments to examine communities and food webs to discover which species or interaction most influenced population and community dynamics. They manipulated species that natural history or energetic

analyses suggested were important. They used either "press" (continual) or "pulse" (singular) experiments to manipulate populations of single species and then followed the response of other species within the food web. The philosophy of these studies was to simplify the complexity of natural systems with the assumption that many species and links between species were unimportant to dynamics. Paine tested this assumption and found that indeed many links between species were weak (essentially zero).

Experimental analyses of food webs are designed to identify species and feeding links that most influence population and community dynamics. These alone are placed into an "interaction web" that, in theory, encompasses all the elements that most influence the distribution and abundance of member species. However, unlike connectivity webs, key species are identified through experiments rather than diet frequency or energy transfer. The initial process of choosing certain species and interactions for experiments and excluding others is subjective, optimally based on strong intuition and a rich understanding of natural history. As the researcher learns more, some elements are discarded and others are subject to further experimentation. Eventually, the community is distilled into an interaction web, a subset including only species that dominate biomass and regulate the flow of energy and matter.

This approach has been used by experimental and theoretical ecologists to produce a rich understanding of the processes that most influence their communities. They have been remarkably fruitful and have introduced many food web paradigms that go to the center of ecology, for example, keystone species, the intermediate disturbance or predation hypothesis, the size-efficiency hypothesis, top-down and bottom-up control, trophic cascades, and apparent competition.

However, this approach is not without limitations. Three major problems stand out. First, many statistical shortcomings can beset experimental manipulation of food webs. For example, replications are commonly difficult (time-consuming and expensive) and therefore experiments often lack the statistical power necessary to avoid type II statistical errors (significant biological differences exist among treatments but low sample size precludes their detection statistically). Second, the number of possible experiments is almost infinite. Which ones should be conducted, and which species should be manipulated?

The third and perhaps most troublesome problem is that experiments isolate a subset of species and links from the community food web, largely ignoring how manipulations interact with the remainder of the community. Thus, unobserved, indirect, or higher order interactions may exert important effects on the dynamics of experimental species and, in theory, make the outcome of experiments indeterminate. For example, predators are thought typically to suppress their prey. However, if a predator is omnivorous, not only eating the prey but also consuming a more efficient predator on the same prey (i.e., it is an "intraguild predator;") it may actually relax the predation load on their shared prey, thus increasing the shared prey's abundance. For example, guilds of biological control agents must be carefully structured because some species eat not only the host but also other predators/parasitoids and thus their presence decreases the number of control agents and increases target pest populations. Many other

cases exist in which consumers, *via* such intraguild predation, may indirectly facilitate its prey while concurrently exploiting it *via* direct consumption. Another example of indirect effects mediated by other than studied “focal species” is shown by the interaction between Australian bell miners and their homopterian food (“lerp.”) After these birds were removed experimentally, the insects first increased greatly in number and then vanished when other bird species invaded the now undefended miner territories. Thus, the apparent effect of leaf miners on lerp insects (here, suppression or facilitation) depends on when the insects were surveyed. Such complications have undoubtedly interfered with clear interpretation of many experiments. The caveat is clear: Experiments can be indeterminate, producing contradictory, counterintuitive, or no results, depending on the relative strengths of the direct and indirect effects.

These problems can be anticipated and partially negated with the application of good intuition of the natural history of the system and important mechanisms. Such intuition is a product of intimate empirical knowledge gained through observation and guided by a conceptual awareness of which interactions are potentially important. Initially, this process is essential to design the appropriate experiments and identify, which species and trophic links may be dynamically important. At the end, experiments must be interpreted in a food web context to assess possible indirect and higher order effects. Experimental results must be complemented with good descriptive, mechanistic, and comparative data to produce a deep understanding of the system. This is one role for energetic and dietary data. Experiments in the absence of natural history often do not succeed and may mislead.

The important messages from this section are that the complex food webs of natural communities can be simplified and understood by isolating key species and links into “interaction webs;” experiments are absolutely necessary for this process, and experiments must be designed and interpreted with sound intuition based on natural history and theory.

Omnivory and the Structure of Food Webs

It is necessary to discuss feeding connections in more detail. Empirical research and logic have shown that the vast majority of consumers on this planet are very omnivorous, feeding on many types of food throughout the entire food web. This is not to say that all species are so catholic in their diets. Specialists abound, for example, many herbivores or parasites consume only specific plants or hosts. However, these form a minority of consumers. The ubiquity of omnivory carries many implications for our efforts to produce theory and models to understand how food webs operate in and shape natural systems.

Omnivory occurs ubiquitously when consumers eat prey from general classes of prey, such as arthropods, plankton, soil fauna, benthos, or fish. The existence of multiple trophic types within these classes causes consumers to feed on species from many trophic levels. For example, “arthropodivores” eat whatever properly sized arthropods are available (e.g., predaceous spiders and insects and insect parasitoids, herbivores, and detritivores) without pausing to discriminate among their

prey according to trophic status. For example, in the Coachella Valley desert delineated by Polis (1991) in more than 10 years of study, predaceous and parasitoid arthropods formed 41% of the diet of vertebrate and 51.5% of invertebrate arthropodivores, with the remainder of the diet being herbivorous and detritivorous prey. Similarly, inspection of diet data of planktivores, piscivores, “insectivores,” carnivores, or benthic feeders reveals that such different channel omnivory is almost universal with the exception of those few taxa that specialize on a few species of prey. Many other systems are dominated by omnivores, for example, Arim and Marquet (2004) found omnivorous links between 86.7% and 72.8% of intermediate and top predators, respectively, in a set of natural food webs. For intermediate predators this was significantly greater than the 46.2% predicted from null models of the same food webs, but for the top predators the difference was not significant (expected = 67.7%), but is still large.

Another important type of omnivory occurs when consumers eat whatever resources are available or abundant at a particular time or place, regardless of their trophic history. When analyzed, the diet of a single species usually shows great differences through time (e.g., seasonally) and space (patches or habitats). Prey exhibit three general phenologies: pulsed (population eruptions lasting a few days or weeks), seasonal (present for 2–4 months), and annual (available throughout the year). Feeding on prey from all three phenologies produces diet changes over time for almost all nonspecialist consumers. Furthermore, many (most?) vertebrates opportunistically switch from plant to animal foods seasonally. For example, granivorous birds, rodents, and ants primarily eat seeds but normally feed on the abundant “arthropods” (= insects from all trophic levels and spiders) that appear during spring. Alternately, many omnivorous, arthropodivorous, and carnivorous species consume significant quantities of seeds or fruits. In the Coachella Valley, 79% of 24 primary carnivores eat arthropods and plants; for example, coyotes eat mammals (herbivorous rabbits, rodents, and gophers; arthropodivorous antelope and ground squirrels; carnivorous kit foxes and other coyotes), birds (including eggs and nestlings, e.g., carnivorous roadrunners; herbivorous doves, and quails), snakes, lizards, and young tortoises as well as scorpions, insects, and fruits. In New South Wales, 15 of 27 ant species are “unspecialized omnivores” eating nectar, seeds, plant parts, and a broad range of living and dead insects, worms, and Crustacea. Overall, it appears that most consumers eat whatever is available and whatever they can catch.

“Life-history” omnivory describes the great range of foods eaten during growth and ontogeny by most species (the “age structure component” of dietary niche breadth). Such omnivory includes abrupt diet changes in species undergoing metamorphosis (e.g., many marine invertebrates, amphibians, and holometabolic insects) and gradual diet changes in “slowly growing species” (e.g., reptiles, fish, arachnids, and hemimetabolic insects). Changes at metamorphosis can be great; for example, 22% of the insect families in the Coachella Valley desert community undergo radical change in diet – larvae are predators or parasitoids and adults are herbivores. Although not as dramatic, significant changes characterize slowly growing species so that differences in body size and resource use among age classes are often equivalent to or greater than

differences among most biological species. Life history omnivory expands the diet of species throughout the entire animal kingdom with the exception of taxa that use the same food species throughout their lives (e.g., some herbivores) and those with exceptional parental investment (e.g., birds and mammals) so the young do not forage for themselves.

“Incidental omnivory” occurs when consumers eat foods in which other consumers live. Thus, scavengers and detritivores not only eat carrion or organic matter but also the trophically complex array of microbes and macroorganisms that live within these foods. Frugivores and granivores commonly eat insects associated with fruits and seeds. Predators eat not only their prey but also the array of parasites living within the prey. In each case, consumers automatically feed on at least two trophic levels.

These types of omnivory are widespread and common. Their ubiquity poses many questions. First, how does omnivory affect food web structure? Most obviously, it increases complexity and connectivity. Second, can we ignore omnivory in the analyses of food webs? By its very nature, omnivory causes consumers to have a great number of links, each of which may be numerically unimportant in the diet. For many reasons delineated later, we cannot arbitrarily ignore apparently minor diet links if we hope to understand dynamics.

Patterns of Biomass and Energy in Food Webs

Primary productivity is among the most fundamental biological processes on the planet, transferring the energy locked in light and various inorganic molecules into forms useful to sustain producers and the diversity of consumers. What factors control primary productivity and regulate its distribution among plants, animals, and microbes? How do changes in primary productivity work their way through a food web to alter the abundance and biomass of herbivores to predators and detritivores? As discussed later, such key questions are best assessed using a food web approach. However, considerable controversy exists regarding the exact way that food web structure influences community and ecosystem dynamics.

Trophic Levels, Green Worlds, and Exploitative Ecosystems

Ecological research has amply demonstrated that food webs in nature contain hundreds to thousands of species, reticulately connected *via* multiple links of various strength to species in the autotroph and saprophagous channels and in the same and different habitats; omnivorous, age-structured consumers are common. Nevertheless, much food web theory still relies on the idealization of trophic levels connected in a single linear chain (plant herbivore carnivore). Here, we evaluate this simplification and some of its implications. In particular, we focus on two grand theories whereby food webs are considered to be central to community organization.

The trophic level ideal in a simple linear food chain has had great appeal. Trophodynamics sought to explain the height of the trophic pyramid by reference to a progressive attenuation of energy passing up trophic levels, envisioned as distinct and functionally homogeneous sets of green plants,

herbivores, primary carnivores, and, sometimes, secondary carnivores. This is a bottom-up community theory based on the thermodynamics of energy transfer. In counterpoint, Hairston, Smith, and Slobodkin’s green-world hypothesis (GWH; Hairston *et al.*, 1960) is primarily a top-down theory, with abundance at each level set, directly or indirectly, by consumers at the top of the chain. Thus, carnivores suppress herbivores, which releases green plants to flourish. These and earlier theoretical studies attempted to simplify food webs greatly to find generalities among them. GWH reduced complex webs to food chains in which species were pigeonholed into specific trophic levels. This allowed for predictions on how higher trophic levels (e.g., predators) influenced the dynamics of lower trophic levels (e.g., primary producers).

Oksanen *et al.*’s (1981) exploitation ecosystem hypothesis (EEH) generalizes GWH to fewer or more than three trophic levels. Trophic cascades are examples of food chains that behave approximately according to EEH. Trophodynamics and EEH each rely on the integrity of trophic levels and the existence of a single, albeit different, overwhelming mechanism that imposes structure on ecosystems. EEH proposes a conceptual framework of “exploitation ecosystems” in which strong consumption leads to alternation of high and low biomass between successive levels. Even numbers of “effective” trophic levels (two or four levels) produce a low-standing crop of plants because the herbivore population (level 2) flourishes. Odd numbers (one or three levels) result in the opposite effect: Herbivores are suppressed and plants do well. Proponents of EEH differ on subsidiary points, the first being the role of bottom-up effects in which primary productivity sets the number of effective levels. The most productive systems support secondary carnivores and therefore have four levels and low-standing crops of plants. Low-productivity systems (e.g., tundra) support only one effective level – plants. More productive habitats (e.g., forests) have three. Productivity is never high enough to support more than three effective levels on land or four in water. Other studies argue that physical differences between habitats, by affecting plant competition and consumer foraging, cause three levels on land and four in water.

EEH definitions of trophic levels are distinctive and adopt the convention that trophic levels occur only if consumers significantly control the dynamics or biomass of their food species. Without top-down control, consumers do not comprise an effective trophic level regardless of biomass or number of species involved. Supporters of EEH have noted that only when grazers regulate plants are grazers counted (as a trophic level), and only when predators regulate grazers they are fully counted. Thus, considerations of food chain dynamics do not become stranded in the immense complexity of real food webs. Whereas, GWH trophic levels are based on energy deriving from primary productivity. Thus, “trophic level interactions ... weight particular links in the food web for their energetic significance.” A trophic level is “a group of organisms acquiring a considerable majority of its energy from the adjacent level nearer the abiotic source.” Despite these differences, both EEH and GWH theory argue that variability in the number of trophic levels exerts profound consequences on community structure and dynamics.

Considerable controversy exists as to the validity of GWH and EEH. The consensus has swung against these grand

theories. Numerous arguments and empirical observations suggest that such processes operate occasionally in water but never on land. Basically, the complexity observed in natural systems does not conform to the reality of simple trophic levels. It appears that the notion that species clearly aggregate into discrete, homogeneous trophic levels is a fiction, arising from the need of the human mind to categorize. Especially in speciose systems, groups of species with diets of similar species do not occur. Omnivory, ontogenetic and environmentally induced diet shifts, and geographical and temporal diet heterogeneity all obscure discrete trophic levels. Even plants do not easily form a single level; higher plants have diverse crucial trophic and symbiotic connections with heterotrophs and many phytoplankton are mixotrophic, obtaining energy *via* photosynthesis, absorption of organic molecules, and ingestion of particles and bacteria. With increasing diversity and reticulation in webs, trophic levels blur into a trophic spectrum rather than a level. These species-individualistic and continuous “trophic spectra” are a reasonable alternative to the simplistic construct of homogeneous trophic levels.

Complex Food Webs, Multichannel Omnivory, and Community Structure

Polis and Strong (1996) offered a framework in the context of functioning community webs as an alternative to theories based on discrete trophic levels. Substantial evidence indicates that most webs are reticulate and species are highly interconnected, most consumers are omnivorous on foods (frequently on both plants and animals) across the trophic spectrum during their life history, most resources are eaten by many species across the trophic spectrum, plants are linked to a variety of species *via* trophic mutualism, most primary productivity becomes detritus directly, detrital biomass re-enters the autotroph channel of the web when detritivores and their predators are eaten by consumers that also eat species in the herbivore channel, and species are often subsidized by food from other habitats.

They proposed that such trophic complexity pervades and generally underlies web dynamics. High connectance diffuses the direct effects of consumption and productivity throughout the trophic spectrum. Thus, consumer and resource dynamics affect and are affected by species at multiple positions along the trophic spectrum rather than interacting only with particular trophic levels. Consumer density is elevated and they often persist by eating resources whose abundance they do not influence (i.e., the interaction is “donor controlled.”)

Such dynamics are illustrated by focusing on top-down interactions. Some consumers exert “recipient” control on some resources and, occasionally, produce trophic cascades. Polis and Strong (1996) suggest that such control is often enabled by omnivorous feeding and various consumer subsidies which are usually donor controlled. Here, the transfer of energy and nutrition affects dynamics; numerical increases in consumer abundance occur from eating diverse resources across the trophic spectrum in the autotroph channel, from detritivores and detritus, the saprovores channel, other habitats, and across their life history. Consumers, so augmented, exert recipient control to depress particular resources below

levels set by the nutrition traveling through any particular consumer–resource link (analogous to the effects of apparent competition). Top-down effects arising from such donor-controlled, “multichannel” omnivory are depicted in Figures 2 and 4. Strong consumer-mediated dynamics occur precisely because webs are reticulate and groups of species do not form homogenous, discrete entities.

Multichannel omnivory has two essential effects on the dynamics of consumers, resources, food webs, and communities. First, it diffuses the effects of consumption and productivity across the trophic spectrum rather than focusing them at particular trophic levels: It increases web connectance, shunts the flow of energy away from adjacent trophic compartments, alters predator–prey dynamics in ways *contra* to EEH assumptions, and thus disrupts or dampens the ecosystem control envisioned by EEH. For example, Lodge showed that omnivorous crayfish can depress both herbivorous snails (consistent with GWH and EEH) and macrophytes (inconsistent).

Second, omnivory can affect dynamics in a way analogous to apparent competition. Feeding on “non-normal” prey can increase the size of consumer populations (or sustain them during poor periods), thus promoting top-down control and depression of “normal” prey. Frugivory, herbivory, granivory, detritivory, and even coprophagy form common subsidies for many predators. Vertebrate carnivores consume amply from the lower web without markedly depleting these resources. Does energy from fruit help carnivores depress vertebrate prey (e.g., herbivores)? Arthropodivory by seed-eating birds is the norm during breeding, with insect protein crucial to nestlings. Arthropodivory by granivores (and conversely, granivory by arthropodivores) must enhance bird populations and thus reduce seeds (arthropods) to a greater degree than if diets were not so augmented.

Trophic Cascades or Trickle

One prediction of GWH and EEH is that communities are structured by trophic cascades. Trophic experiments to test cascades use two methods: a bottom-up approach by increasing a resource (e.g., nitrogen or phosphorus) or a top-down approach that adds a top predator to a system. In the former, trophic cascades lead through a set of intermediate steps to increase densities of particular species or trophic groups higher in the web. In the latter, the top predator suppresses the trophic level below leading to increased densities two levels below. Thus, the expected responses should follow GWH/EEH predictions where alternating trophic levels are arranged with opposite densities (common – rare – common). For example, in a tritrophic (three-level) food chain, an increase in nutrients results in increases in the primary producer (plant) trophic level, decreases in the primary consumer (herbivore) level, and an increase in the top consumer level.

Proponents GWH and EEH suggest that strong trophic cascades occur in numerous food webs whereby entire trophic levels alternate in abundance *via* cascading food web interactions. However, empirical evidence shows that such cascades rarely or never occur on land and are apparently only present in a few aquatic communities. What determines whether a strong trophic cascade occurs or food web interactions weaken

to become a trophic “trickle”? One major consideration is the efficiency of energy and resource transfer up the food chain. Highly efficient transfers lead to large numbers of top predators/consumers that would affect top-down control and strong cascades. Any factors that decrease the efficiency of energy/resource transfer would lessen the top-down control. In accordance with Polis and Strong's (1996) multichannel omnivory, an increasing list of factors have been examined to explain the differences between GWH/EEH expectations and experimental results and observations of natural communities that generally show weak or no trophic cascades. These factors include omnivory, ontogenetic shifts, edibility, food quality, ecological stoichiometry, cannibalism, disease, body size refuges (for prey), allochthonous resources, seasonality, life-history characteristics, predator avoidance behavior, and spatial and temporal heterogeneity in the availability of resources.

Current Topics/Trends in Food Web Studies

Here, relatively under-studied aspects of food webs perceived to be central to understanding populations, communities, and ecosystems are identified. Some of the topics are now focal points for food web research, both empirical and theoretical.

Food Webs as Open Systems

Recent methods of tracing stable isotopes through a food web can provide much information on feeding relationships and on the sources of productivity that drive communities. For example, using stable isotopes or diet data, one can determine whether a community utilizes resources that originate in the benthic or pelagic zones of lakes or both.

Virtually all natural systems are open and can exhibit tremendous spatial heterogeneity. Great spatial heterogeneity exists and nutrients and organisms ubiquitously move among habitats to exert substantial effects. However, food web studies have tended to focus on communities at a given site without regard to potential interactions with the surrounding habitat. Thus, little attention has been given to the fact that food web structure and dynamics are influenced by the movement of resources and organisms across habitat boundaries. Trophic linkage between habitats depends on the degree of differentiation in habitat structure and species composition. Systems that are moderately different tend to have broader transition zones and greatly overlap in species composition; these include grassland-forest, littoral-sublittoral, and benthic-pelagic zones. Habitats that have significant and abrupt changes in structure and species composition occur at the land-water interface.

Moving resources (energetic or nutrients) can be utilized by different trophic types and the organisms that move across boundaries may also differ trophically (e.g., predators and prey). Studies of communities on island systems have shown that most of the allochthonous inputs (i.e., input from other habitats) from the ocean are available to detritivores, predators, and scavengers. Such movement of nutrients, detritus, food, prey, and predators is absolutely ubiquitous, occurring in virtually all communities and across all habitats. Some

systems heavily dependent on allochthonous inputs include caves; mountaintops; snowfields; recent volcanic areas; deserts; marine filter-feeding communities in currents; soil communities; the riparian, coastal areas; lakes; rivers; and headwater streams that receive watershed inputs. However, all systems depend on allochthonous inputs. For example, recent work shows that plant productivity in both the Hawaiian Islands and the Amazon forest is dependent on phosphorus input from thousands of miles away (China and Africa, respectively). The migrations (e.g., songbirds or geese) and movement of herbivores (e.g., wildebeest or hippopotamuses) can also result in large energetic flows across habitats.

Allochthonous inputs into the top level include carrion or carcasses, the movement of prey species into the habitat, and movement of predators across habitats. For example, the Allen paradox describes cases in which secondary production within streams is insufficient to support levels of fish production in them. Similarly, studies of coyote populations along the coast in Baja California demonstrate that they are highly subsidized by inputs from the ocean (about half of their diet) and are able to maintain three to more than 10 times higher density than in adjacent inland areas. Predators moving along the interface between ecosystems (i.e., shorelines, riverbanks, and benthic and pelagic systems) can utilize resources across habitat. The river continuum concept argues that allochthonous resources entering into small headwater streams provide much of the productivity for organisms downstream in larger order streams. These allochthonous resources include prey, dissolved and particulate organic matter, and litter fall. Such inputs also power estuarine systems in which rivers carry allochthonous inputs into estuaries. Similarly, runoff from terrestrial systems into aquatic systems (and vice versa) provides litter, dissolved and particulate organic matter, and prey.

Spatial coupling can be key to dynamics. For instance, arboreal anole populations, subsidized by insects imported from light gaps, increase so as to suppress some predators and herbivores. Abundant detrital kelp from the sublittoral zone promotes dense intertidal limpet and urchin populations that then graze noncoralline algae to low cover. Allochthonous subsidies commonly influence stream systems: Leaf fall subsidizes herbivores, which in turn depress algae. Spiders that live along the coasts of streams, rivers, lakes, or the ocean are often very dense because they feed on aquatic insects. These spiders can then depress herbivores and thus increase the success of plants on which they live. Such spatial subsidies appear to be the foundations of most of the well-known trophic cascades. All these interactions are donor controlled: Consumers do not affect the rate of import, availability, or dynamics of the allochthonous resources. However, subsidies allow consumers to be more abundant than if supported solely by *in situ* resources, with consequent suppression of *in situ* resources decoupled from *in situ* productivity.

A common thread that has begun to link most thinking on food webs is that they are dynamical systems that vary over space and time. This approach has been liberating to ecologists, both empirical and theoretical. Recent empirical studies have found that communities and food webs contain multiple pathways that allow them to respond to environmental change and disturbance.

Detritus

Little of the energy fixed by plants passes directly into the grazing food chain – herbivores eating plants and then eaten by carnivores. Most of this primary productivity is uneaten by herbivores (median >80% on land, ~50% in water). What happens to this dominant chunk of the world's productivity? Is the detrital web a self-contained sink internally recycling energy and nutrients or a link that affects the population dynamics of the larger species?

Uneaten plants (and animals) enter the detrital web, in which they are processed by microbes, fungi, and some animals. Although some ecosystems are net accumulators of undigested biomass (e.g., carboniferous bogs and forests that supply today's oil and gasoline), most ecosystems do not accumulate plant biomass. Rather, it is soon digested by detritivores, with nutrients and energy passing through "functional compartments" composed of diverse microbes and animals. Several factors regulate the flow and availability of detritus to detritivores and then onto other consumers. A major question is rather whether the detrital community is a sink that metabolizes most of this energy or a link that passes this energy up the food chain.

An unknown fraction of detrital energy and nutrients re-enter grazing food chains when some detritivores are eaten by predators that also eat herbivores (e.g., a robin eats an earthworm). Such "detrital shunts" are common, interweaving energetics and dynamics of biophages and saprophages. Bypassing herbivores, this linkage can affect herbivore regulation in a manner analogous to the spatial subsidies to consumers discussed previously. Predator populations, subsidized by detritivorous prey, can increase and suppress other predators or herbivores.

The exact effect of detrital shunts depends on the relative benefits for each species and where detritus re-enters (to producers, herbivores, and intermediate or higher consumers). For example, nutrients from detritus greatly influence plant productivity; models show that a 10% reduction in detritus can cause a 50% reduction of plant biomass. The dynamics of consumer control within the detrital web and those produced by infusion of detritivores into the grazing web are undoubtedly crucial to community structure and dynamics. For example, detrital shunts to predators in the grazing chain can create the appearance of a simple linear trophic cascade, but with the difference that nutrition from detritivores sustains or elevates predators to levels sufficient to suppress herbivores.

Age Structure Effects in Food Webs

Almost all species display complex life cycles, marked by moderate to radical changes in diet and habitat; such life histories fundamentally must affect every species with which they interact. However, our understanding of how age- and stage-structured processes affect food webs and communities is embryonic.

Life history omnivory describes shifts in diet during development; often they are accompanied by ontogenetic changes in habitat. Diet can change substantially either discontinuously (e.g., at metamorphosis) or slowly with growth. Such life histories are widespread; an estimated 80% of all animal species undergo metamorphosis. Changes in resource use can be dramatic (e.g., predaceous juveniles, plant-feeding

adults in parasitoids and many other insects, and herbivorous tadpoles and predaceous frogs and toads), with prey size variation as great as three or four orders of magnitude. Even among nonmetamorphic species, diets change greatly with age, with diet differences among age classes often more distinct than those among most species. Thus many species can be classified as life-history omnivores, which are species that feed on different trophic levels over their various life stages.

Overall, complex life histories and age structure omnivory can exert diverse and profound effects on the dynamics of populations and food webs. For example, they can either impede consumer control or amplify resource suppression *via* dynamics similar to those of spatial subsidy or detrital shunts.

The Roles of Nutrients and Stoichiometry

Animals require both energy and a variety of "nutritional requisites" to grow, complete their life cycle, and reproduce. Important nutrients include nitrogen, phosphorus, some trace elements, fatty acids, and vitamins. Nitrogen is an integral component of many essential compounds: It is a major part of amino acids, the building blocks of proteins, including the enzymes that control virtually all cellular processes. Other nitrogen compounds include nucleic acids and chlorophyll. Phosphorus is used for adenosine triphosphate (ATP, the energy currency of all cells), nucleic acids (DNA and RNA), and phospholipids, particularly in cell membranes.

The availability of nutritional requisites constrains growth and reproduction in virtually every species. Nitrogen and phosphorus are particularly important. The ratio of carbon to nitrogen (C:N) in plants ranges from 10:1 to 30:1 in legumes and young green leaves to as high as 600:1 in some wood. The C:N ratios in animals and microbes are much lower, ordinarily between 5:1 and 10:1. Such differences in C:N ratios between plants and their consumers lower the rate of decomposition by microbes. There is ample evidence that heterotrophs chronically lack adequate nitrogen to grow or reproduce optimally. The importance of nutritional restriction is reinforced by the foraging literature that clearly shows that herbivores choose their foods based on nutrient as well as energy content.

In many cases, phosphorus availability constrains herbivore success. The Redfield ratio describes the approximate stoichiometric mix (110 C:250 H:75 O:16 N:1 P) of elements found in marine systems. In particular, the N:P ratio crucially determines productivity and species composition. Thus, energy (C–C bonds) and nitrogen could be abundant, but neither individuals nor populations grow maximally because phosphorus is insufficient. Because phosphorus is essential to cell division (and thus reproduction), a high N:P ratio especially limits the growth of organisms that have high potential $r_{\max}$, such as most herbivores and detritivores. These organisms are key to the potential regulation of plant biomass (and "detritus.") Evidence suggests that high N:P ratios can impede trophic cascades. For example, *Daphnia*, a key to many lake cascades, respond sufficiently rapidly to phytoplankton productivity to depress plant biomass. In lakes with inadequate phosphorus, slower growing copepods replace *Daphnia*; these copepods do not have the reproductive capacity to depress phytoplankton biomass.

Ecologists are beginning to understand how stoichiometry and nutritional balance affect population and food web dynamics. Nevertheless, it is extremely likely that herbivore growth is often less than maximal solely because their environment does not provide sufficient quantities of all key nutritional requisites. In fact, the greatest disparity in biochemical, elemental, and stoichiometric composition in the entire food web occurs at the link where herbivores convert plant material into animal tissue. The implication is clear: Even in a world full of green energy, many or most herbivores cannot obtain enough requisite resources to grow, survive, or reproduce at high rates. Nutritional shortages regulate herbivore numbers and often limit their effects on plant biomass.

Recent theoretical studies of the role of food quality in terms of edibility and nutrient content show that low food quality can greatly influence consumer–resource interactions. This has two important consequences. First, low food quality reduces the growth rate of the consumer, making that interaction more stable. Second, in systems in which multiple resources could be limiting, the addition of large amounts of a single resource (such as nitrogen or phosphate) may increase that resource to a level at which it is no longer limiting; however, a second resource would become limiting and so on. This sequential limiting of resources means that the addition of a single resource would not push the system into highly unstable dynamics, reducing the probability that the “paradox of enrichment” occurs. Rosenzweig introduced the concept of the paradox of enrichment to explain the addition of a resource leading to the collapse of a consumer–resource interaction. This happens because the addition of the resource drives the population of the consumer to a higher level that results in overcompensation by the consumer (predator) driving the resource (prey) extinct. However, most systems have several potentially limiting resources. For example, Leibold’s study of ponds found that nitrogen additions do not lead to strong trophic cascades or the paradox of enrichment because light becomes limiting with relatively modest nitrogen additions.

Interaction Strength

One goal of functional webs is the quantification of interaction strengths within food webs. Various definitions have been used for “interaction strengths.” In Lotka–Volterra models, interaction strengths are due solely to the direct interactions between species pairs and are measured on a per capita basis. Estimations of the strength of these direct interactions are fraught with difficulties. Measurements in artificial systems may not allow for behavioral responses. For example, Sih has shown that prey species have different escape mechanisms or routes depending on the species of predator. Thus, when in the presence of two predators, the response of a prey may result in its increased susceptibility to one or the other predator due to a behavior that is not evidenced when only the one predator is present.

Measurements in natural systems are also problematic because they may not account for indirect interactions. Many studies have elucidated the interaction strength among pairs of species. However, indirect effects may play a strong role in determining the realized interaction strength. Thus, Paine has

argued that interaction strengths should always be measured in the field with the full complement of natural species present and that these measurements should incorporate all indirect effects. The realized interaction strength accounts for all direct and indirect interactions. For example, predator–prey interactions are functionally negative due to the direct effect. However, the indirect effect of a predator may reduce the number of competitors of the prey species, thus resulting in an overall positive interaction strength (direct + indirect effects). Therefore, potentially strong indirect effects can make mechanistic interpretation of experimental results among species difficult.

Path analysis, a new statistical method, has been used to evaluate causal hypotheses concerning the strengths of interactions in many systems. Path analysis is essentially a multiple regression on each species in which specific causal relationships (e.g., alternative food web configurations), specific experimental treatments, and other interactions are diagrammed in a community interaction web. The community interaction is essentially a food web to which nonconsumptive interactions, such as pollination, competition, and mutualisms are added. Hypotheses for the causal relationships between pairs of species not directly linked can become quite complicated. However, path analysis can test different hypothesized community web structures by accounting for both direct and indirect relationships. Then, experimental manipulations (e.g., species removals or additions) can test predictions of the path analysis.

Can Energetic Webs Provide Insight into Population and Community Dynamics?

A problem in food web studies is how to connect the great amount of quantitative information in energetic webs to population and community dynamics described by functional webs. Much progress would occur if we could determine the dynamical importance of a particular species or feeding link from an inspection of the magnitude of energy transfer or diet composition. Unfortunately, no clear answer is forthcoming. In fact, it appears that even highly quantified information such as the number of calories passed along a certain pathway or the frequency of prey in the diet of a consumer conveys little information about the dynamics of interacting populations because these descriptive parameters do not correlate with interaction strength.

There is no clear rationale to argue that food web dynamics and energetics are necessarily correlated; indeed, logic and evidence suggest that dynamics often cannot be predicted from data on diet or energy flow. The degree of resource suppression is not a function of energy transfer. Consumer regulation of populations need involve little energy transfer and few feeding interactions. For example, removing predatory rats from New Zealand islands increased lizard abundance 3–30 times although lizards formed <3% of rat’s diet. Key regulatory factors may produce much less overall mortality than other factors. Brief, intense predation episodes may net little energy for the predator but may be central to prey dynamics. The consumption of young stages (seeds, eggs, and larvae) may provide trivial energy to a consumer but can

greatly depress prey abundance. Pathogens and parasites form an extreme example: They take little energy, even when they decimate their host populations. In a well-studied food web of the marine benthic community in the Antarctic, Dayton showed that the species apparently exerting the strongest effects on the structure and dynamics of this community would be deemed unimportant from analyses of diet, energy transfer, or biomass.

Such discoveries have stimulated many to argue that, without experimentation, one cannot *a priori* decide which are strong or weak links. An apparently weak link (in terms of diet or energy transfer) can be a key link dynamically, and an important energetic link may affect dynamics little. No necessary concordance of dynamics with either dietary or energetic measures exists. This insight counters the use of energetics to recognize strong interaction links.

Modeling Food Webs

To many ecologists, early food webs of Forbes, Summerhayes, and Elton and those of Lindeman emphasized the overwhelming complexity of natural systems and the need to simplify them into distinct trophic groups. This perspective was culminated in the green-world hypothesis of Hairston *et al.* (1960). Oksanen *et al.*'s (1981) EEH expanded this view for ecosystems that had fewer or more than three trophic levels and for which the exact number of trophic levels was set by productivity. The top level would then regulate the one below it and this would release the one below it, etc. In this sense, both GWH and EEH suggested that all ecosystems are essentially regulated from the top-down by predation.

Lindeman envisioned the food web (or as he called it, the "food-cycle") as a dynamic system in which energy and nutrients are transferred from one trophic level to the next and recycled. This was an important departure from simply determining feeding connectedness (and from the GWH) in that ecosystems could be regulated from the bottom-up by the flow of energy and materials from the level below. However, much more information and data are required to quantify the transfer of energy (and material) through food webs, but this view allows for a more analytical approach.

MacArthur focused the attention of ecologists on the trophic-dynamic approach with his hypothesis that increasing complexity of community organization leads to increasing dynamic stability. The reasoning was simple: When predators have alternative prey, their own numbers rely less on fluctuations in numbers of a particular species. Where energy can take more routes through a system, disruption of one pathway merely shunts more energy through another, and the overall flow continues uninterrupted.

MacArthur's analytical approach linked community stability to species diversity and food web complexity and it stimulated a flurry of theoretical, comparative, and experimental work. This work may be divided into two contemporary approaches that use food webs to study community structure. The first approach involves the study of the properties of food web diagrams with the goal of uncovering general patterns that suggest mechanisms of community stability. This is done both by comparing food webs from natural

communities and by the use of simulation and mathematical modeling to study hypothetical food webs. This research has yielded much of the terminology now associated with food webs and generated a body of food web theory that includes many hypotheses about community structure.

The second approach, which grew from early theoretical and experimental community studies, involves the dynamical analysis of food webs to determine not only the pattern of interactions among the populations in the community but also the relative strengths of those interactions. Dynamic food web analysis also seeks to reveal interactions that are not obvious from simple food web diagrams, so-called indirect interactions. This approach requires the careful merging of experimental and theoretical approaches.

The simplicity of the GWH enabled it to be a reasonable starting point to examine the dynamics of food webs. In general, dynamical models are rooted in a tradition based on the application of Lotka-Volterra equations to communities and advocated by May (1973). One of the major conclusions from these phenomenological models is that complexity (e.g., omnivory and long chains) causes instability in model systems. This conclusion was viewed with skepticism by empiricists because observations from field studies (such as work by MacArthur) suggested that increased complexity should result in increased stability. Recent theoretical investigations into the relationship between stability and complexity have found that assumptions and structure of earlier models may have biased them toward decreased stability with increasing complexity.

Early theoretical studies of interactions and consequences of these interactions in food webs were based on equilibrium dynamics of Lotka-Volterra models. The assumption that ecological systems or species populations have some "equilibrium" around which they fluctuate is totally unrealistic. Furthermore, these early models ignored the central belief of many empiricists that most interactions between species were weak. The outcome of many of these theoretical studies went against common sense intuition and the findings of empirical studies, including that omnivory was destabilizing and therefore rare and that complexity (greater diversity) was also destabilizing. Recent studies that incorporated the findings of mostly weak interactions and nonequilibrium dynamics have found that omnivory and complexity may actually stabilize food webs. This agrees with both the intuition and the current arguments of empiricists who find that many weak interactions occur within food webs and these promote stability.

Recent theoretical studies suggested three factors as important to reduce stability in earlier models: (1) linear Lotka-Volterra equations, (2) using equilibrium solutions to these equations, and (3) the distribution of interaction strengths overly estimated the number of strong links. Many studies have shown that many predator-prey relationships are not linear, but instead predators exhibit saturation such as described by a Holling's type II functional response. Current models take advantage of this and use energetic uptake rates that saturate based on body size relationships. Also, equilibrium solutions to Lotka-Volterra relationships can give biologically unrealistic results because the assumption of equilibrium does not appear to hold in many predator-prey relationships. May and others used a uniform distribution in randomly created model food webs, which resulted in their

webs having an over-representation of strong interaction compared to natural systems. This convention was based on the few early studies that examined the distribution of interaction strengths and suggested that there is a bias for weak interactions. May acknowledged that if the distribution of interaction strengths was not uniform, his results may not hold. Furthermore, recent theoretical studies also suggested that omnivory can stabilize food webs. Paradoxically, researchers using Lotka–Volterra models have found that although on average omnivory decreased stability, those systems in which omnivorous links persisted had the greatest stability. This increased stability may occur in Lotka–Volterra models when randomly created omnivorous links are weak.

In modeling food webs, a key consideration is the functional relationship between a consumer and its resource. As noted previously, Lotka–Volterra consumer–resource relationships are linear (type I). This assumes that the predators do not become saturated and can consume all available prey. Holling introduced nonlinear consumer–resource functional relationships with his disk (now called type II) functional response. This functional response assumes that the capture and consumption/digestion time of prey by the predator limits the amount of prey taken by a predator in a given amount of time. Holling also introduced a third type of functional response (type III) to simulate a predator switching capture of prey when a target prey species becomes rare to a more abundant prey species. Various other functional responses have been introduced, including Ginzburg and Arditi's ratio-dependent functional response. Ratio dependence assumes that the growth rate of the predator is dependent on the ratio of prey and predator densities, whereas in types I–III predator growth rates are dependent only on the prey densities (prey dependent). Ratio-dependent models predict that all trophic levels increase proportionately, whereas prey-dependent models predict the alternating pattern of GWH and EEH. The arguments against ratio dependence arise from the lack of a mechanistic basis for the model. Proponents of ratio dependence argue that the formulation accounts for the different time-scales of reproduction and behavior. They also argue that the formulation is simpler and can account for essential dynamics of food webs without added complexity. Detractors argue that using more mechanistic, albeit more complex, models that can account for realistic interactions is the correct way to proceed. Regardless of these arguments, using intermediate levels of complexity based on realistic mechanisms is the current trend in the food web theory.

Intermediate Levels of Complexity

Community ecology has focused on interactions (mainly competition and predation) between pairs of species that are fundamentally important in food webs. However, these interactions, taken out of context of the larger web, may result in misleading information (due to indirect effects). Highly complex food webs, however, are unwieldy and intrinsically difficult to study in model systems. Thus, Holt and others suggested investigating the dynamics of intermediate (between species pairs and whole food webs) levels of

complexity – so-called “community modules” – that are defined as small subsets of species that are characterized by strong interactions. These modules are also more representative of the levels of complexity (i.e., number of species) examined in experimental studies.

Recent theoretical studies have taken advantage of intermediate complexity by focusing on food web interactions that typify interactions found in real food webs but are common to many food webs. This allows one to examine how indirect effects interact with direct effects to structure food webs. Common types of interactions among sets of species and their resources (modules) are apparent competition, intraguild predation, omnivory, cannibalism, and spatial subsidies.

This modular approach has allowed for various theoretical studies to examine stability of food webs using mathematical approaches. For example, McCann *et al.* (1998) found that adding relatively weak interactions among species could enhance food web stability. They found this to be true for apparent competition, intraguild predation, omnivory, cannibalism, and spatial subsidies.

Are weak interactions typical of food webs? The answer, from the few studies that have specifically examined this question, is yes. For example, in a study on intertidal food webs, Paine found that most interaction strengths are weak. Moreover, knowing that most predators eat 10 to ~100 species of prey suggests that most of these interactions are weak.

One may then ask, what about strong interactions? The answer goes to the heart of one major problem with earlier food web studies. Strong interactions may occur and be a regular component of food webs. However, in almost every case, they appear to be enabled by “multichannel omnivory” (i.e., feeding on many weak links; Polis and Strong, 1996) or are restricted temporally and spatially because they are inherently unstable. However, time and effort constraints and tradition have caused the vast majority of food web studies to ignore the many weak interactions and the spatial and temporal aspects that characterize all systems.

In another theoretical study of food web processes that took advantage of the modular view, Huxel and McCann examined the flow of the allochthonous energetic resources. They found that allochthonous resources may spread evenly throughout the community or may become compartmentalized. High levels of allochthonous resources decreased stability, whereas low levels increased stability. Thus, again a weak link tended to increase stability.

Glossary

Dodder Vine parasites of the genus *Cuscuta* that form haustoria on the stems of their hosts. The unrelated parasitic vine, *Cassytha*, is often referred to as Laurel Dodder.

Endophyte The portion of a parasitic plant that is embedded inside host tissue.

Endophytic parasite Parasites with vegetative bodies that are entirely endophytic and unobservable unless flowering.

Haustrorium (pl. haustoria) The organ found in all parasitic plants that penetrates vascular tissue of the host plant and forms a functional bridge for uptake of water and nutrients from the host.

Hemiparasite A parasite that photosynthesizes.

Holoparasite A parasitic plant that lacks chlorophyll and cannot photosynthesize.

Mistletoe Parasites of the closely related families Loranthaceae or Viscaceae with haustoria that originate as root tissue and penetrate stems or roots (in Loranthaceae) of the host plants.

Mycotrophic (= mycoparasitic) plant A plant that obtains energy through mycorrhizal associations with saprophytic or other biotrophic fungi.

Root parasite Parasites that form haustoria on roots of the host plant.

Stem parasite Parasitic plants that form haustoria on stems of the host.

The Natural History of Parasitic Plants

Parasitic plants are strictly defined by the production of specialized feeding structures, known as *haustoria*, that form a functional bridge into their hosts. Through the haustorium, parasitic plants obtain water, mineral nutrients, sugars, and other host metabolic products. Approximately 3000 angiosperm species (1% of named species) are haustorial parasites; however, this total does not include any plants that feed heterotrophically on fungi (*mycotrophic* plants). Most parasitic plant species are *hemiparasites*; they photosynthesize and are only partially heterotrophic. The degree of heterotrophy in parasitic plants varies between autotrophy and the complete loss of photosynthesis, a condition known as *holoparasitism*.

Other than the presence of haustoria, there are few generalizations that can be made about parasitic plants because they display enormous variability in growth form and host dependence. In most species, haustoria are formed from root tissue of the parasite, but in a few species they are initiated from stem tissue. The haustorium, in turn, can penetrate the root or stem of the host plant. The major life-histories among parasitic plants are distinguished by these differences and they have important ecological implications.

Root parasites are extremely variable in growth form, occurring as trees, shrubs, and herbaceous perennials or annuals. Because their haustoria are often below ground, many root parasites do not demonstrate any obvious indications of parasitism. Experimental studies have compared hemiparasitic plants grown in pots with and without hosts. They found enormous variability among species in their ability to set seed in the absence of a host. The degree of parasitism is extremely variable in root parasites and the increase in seed set for any one species is different depending on the host.

Dodders and some *mistletoes* are both called *stem parasites* because they attach to the stems of the host; however, they have very different life histories. Mistletoes are closely related to root parasites and, in fact, their haustoria are derived from root tissue. Upon seed germination, their haustoria immediately penetrate the host's stem. Mistletoes most often grow on one individual, but in some cases they may sprawl along or hang down from the stems of the host plant. In contrast, dodders are closely related to nonparasitic vines. After germination, dodder seedlings begin to sprawl and twine along the stem of the host, forming haustoria from time to time where the new stems of the dodder contact the host. The rudimentary hypocotyl of the dodder eventually dies and it grows extensively beyond the original point of germination, often using multiple hosts.

All parasitic plants are obligate, requiring a host for survival, growth, or seed production, except for some root hemiparasites. The degree of parasitism is a useful concept for comparing the ecology of related species that vary in their dependence on the host. At one extreme, the ecology of facultative parasites is similar to their fully autotrophic relatives. At the other extreme are a few highly derived lineages of nonphotosynthetic *endophytic parasites* that have all of their plant body within the host tissue emerging only to flower and fruit. Among root holoparasites, there are enormous differences in the amount of biomass that is below ground. Some species are almost exclusively subterranean, growing as long-lived underground tubers, producing only flowers and fruits above ground.

Extremely derived holoparasitic plants are some of the great oddities of nature. In the 10th century, Arabic scholars wrote that parasitic plants performed the actions of animals by feeding from the juices of the host plant; they have the "souls of worms." In 1828, a naturalist named Trattinick proposed

that a separate category should be created to encompass them, the taxonomic equivalent of a mental asylum for the manic and delusional. Certainly the morphology of many holoparasites is nonplant like, and this led some early researchers to call them fungi!

The dissonance experienced on first learning about parasitism in plants betrays a common prejudice in some botanists; plants and parasites are naively regarded as opposites. As a result, parasitic plants have been misidentified and misunderstood. The “bearded-grape” was regarded as a monstrosity and assigned to its own genus; however, it was simply a grape infected by *Cuscuta*! Parasitism in most root hemiparasites was unnoticed by naturalists until very recently making the modern view of parasitic plants only about a hundred years old. In 1969, Job Kuijt’s book, *The Biology of Parasitic Flowering Plants*, abolished many of the mysteries surrounding parasites. In this seminal work, Kuijt provided a critical analysis of all previous research and proposed a conceptual framework for understanding the evolution, morphology, physiology, and ecology of parasitic plants. While Kuijt’s book remains the best authoritative source on the subject, new molecular evidence is being used to resolve the detailed phylogenetic history of parasitism, and a wide range of biochemical, genetic, and molecular approaches are now being applied to better understand parasite biology.

The Parasitic Plant Clades and their Relationships to Other Plants

Phylogenetic relationships between parasitic plant families and their affinities to nonparasitic plants are now well known for most species. A few families of root holoparasites have been difficult to place in a phylogeny because their floral morphologies are unique and they virtually have no vegetative morphology. Molecular phylogenetic study of many parasitic plant groups has been impaired by the fact that photosynthetic and other genes commonly used in plant molecular systematics are missing or evolve at greatly accelerated rate. However, recent studies of plant mitochondrial DNA sequences have resolved 11 or 12 independent origins of haustorial parasitism (Figure 1) distributed throughout angiosperm history.

The Sandalwood order (Santalales) are the largest, most diverse clade of parasitic plants in terms of growth habit, but all retain at least some chlorophyll and photosynthetic ability; in fact, some members may not even be parasitic. This group includes almost 2000 species of trees, shrubs, mistletoes, and at least one species of mainly endophytic mistletoe. Olacaceae and Opiliaceae are composed entirely of trees and shrubs that include both free-living as well as root parasitic members. Santalaceae are also trees and shrubs with both root and stem parasites. The mistletoes belong to one of two large families, Loranthaceae and Viscaceae. The stem and root parasites of Loranthaceae are known as showy mistletoes because of their long, colorful, tubular flowers. Viscaceae, including the “dwarf mistletoe,” *Arceuthobium*, are all stem parasites. In addition to the two mistletoe groups, two other families of Sandalwoods, Misodendraceae and Eremolepidaceae, are stem parasites.

About 1700 root parasitic annuals and perennials are found in what has traditionally been classified as two closely related families, Scrophulariaceae and Orobanchaceae. As a whole, they represent the most diverse clade of parasitic plants in terms of variation in degree of heterotrophy. Traditional Orobanchaceae includes only holoparasites, while the large family Scrophulariaceae (ca. 4500 spp.) has nonparasites, hemiparasites and even some holoparasites. Molecular phylogenies based on chloroplast gene sequences have found the distinction between the two families to be artificial—a strongly supported clade contains all known parasites from both groups, but most of the rest of traditional Scrophulariaceae are not closely related to this group. In other words, Scrophulariaceae appear to be polyphyletic, while the parasitic lineages are quite clearly monophyletic, suggesting a single origin for parasitism in this group. For this reason, dePamphilis and colleagues have proposed to include all of the parasites (plus a few closely related nonparasitic genera) in an expanded Orobanchaceae. Within this large group, holoparasitism appears to have evolved not less than five times. The agriculturally important genera *Striga* and *Alectra* (both mostly hemiparasitic) and *Orobanche* (holoparasitic) are members of this clade, as are the large hemiparasitic genera *Pedicularis*, *Euphrasia*, and *Castilleja*.

The remaining parasitic plant families are not nearly as large or diverse as Orobanchaceae or Santalales. Plants commonly referred to as dodders are found in two families Cuscutaceae and Lauraceae. Cuscutaceae is a family of about 150 species of one genus, *Cuscuta*, that are distributed nearly worldwide. Lauraceae is a large family comprised of mostly nonparasitic trees that also includes one hemiparasitic genus, the vine *Cassytha*. *Cassytha* has about 20 species, most of which are endemic to Australia or Africa, with one species found throughout the tropics. Although strikingly similar in gross morphology, these two parasitic groups originated independently. *Cuscuta* is related to morning glories (Convolvulaceae), in the order Solanales, while *Cassytha* belongs in Laurales, a basal angiosperm order. *Cuscuta* are usually considered to be holoparasites, but very low photosynthetic activity exists in some species; whether or not the chlorophyll-containing species can use their photosynthetic products is unknown.

Approximately 50 species of endophytic holoparasites are found in the traditionally recognized family, Rafflesiaceae. Although considered to be closely related, molecular phylogenies now indicate up to four independent origins (polyphyly) for the genera making up this collection of extreme parasites. Molecular evidence is in agreement with previous studies of pollen morphology that suggested Rafflesiaceae be divided into four families: Rafflesiaceae, Mitrastemonaceae, Apodanthaceae, and Cytinaceae. While floral morphology is diverse for these families, they were previously thought to be related because they all are endoparasites.

Rafflesiaceae includes the largest flower in the world, *Rafflesia arnoldii*, which measures 1m across. *Rafflesia* species only parasitize species of *Tetrastigma* vines (Vitaceae) and have an unusual reproductive biology. Emerging buds develop for approximately 1 year before they open and become receptive to pollinating flies that are attracted to the often fetid scent. Flowers die within 5 days leaving a narrow window of time for pollination to occur. Because of the short flower life span, and because female and male flowers are on separate plants, sexual

Figure 1 *Phylogenetic origins of parasitism in the flowering plants.* Summary tree of flowering plant phylogeny is based on the Neighbor-Joining analysis of mitochondrial gene sequences (*cox1* and *atp A*) conserved in all parasitic plants regardless of photosynthetic ability (T. J. Barkman and C. W. dePamphilis, unpublished). Note that 12 or 13 independent origins are resolved, with parasitic groups containing holoparasites or only hemiparasites shown near their closest resolved nonparasitic group. Mitrastemonaceae + Balanophoraceae is annotated as uncertain (?) because monophyly of this group depends on choice of gene and method of phylogenetic analysis.

reproduction is rare. Rafflesiaceae species are all exceptionally rare and endangered throughout their range, partly due to their reproductive strategy and partly due to habitat loss. As shown in **Figure 1**, recent mitochondrial DNA sequence data suggest that the closest relatives of Rafflesiaceae include the rose order (Rosales).

In contrast to *Rafflesia*, members of Apodanthaceae, *Pilosyles* and *Apodanthes*, produce tiny flowers only a few millimeters wide. Approximately 20 species are included in Apodanthaceae, which are distributed from the southwestern United States throughout the northwestern tropics with restricted localities in Africa, Australia, and the Middle East. Curiously, Apodanthaceae appear to be most closely related to the order Fabales, which includes their primary hosts; various species of legumes.

Cytinaceae include two genera, *Cytinus* and *Bdallophyton*. *Cytinus*, with 6 to 7 species, is distributed in the Mediterranean region, South Africa, and Madagascar and most commonly parasitizes species of *Cistus* (Cistaceae). *Bdallophyton* has only 1 to 4 species that are found mainly in Mexico and parts of Central America usually parasitizing members of the Burseraceae. The closest relatives of this family are classified within the cotton or hibiscus order, Malvaceae. Like the previously mentioned families, Rafflesiaceae and Apodanthaceae, Cytinaceae are not known to cause economic loss because they do not parasitize crop plants.

Mitrastemonaceae are specialists on trees in the family Fagaceae found in southeast Asia north to Taiwan and parts of central and South America. *Mitrastemon* is the only genus included in this family that is made up of two named species

that are totally white. Plants are protandrous and may produce large quantities of nectar.

Another small family, Hydnoraceae, is composed of about 20 species of root holoparasites native to tropical and southern Africa, Madagascar, and South America. Hydnoraceae have traditionally been considered close relatives of Rafflesiaceae, based largely on the shared holoparasitic habit with a reduced vegetative body and highly modified floral structures. However, molecular phylogenies now suggest that Hydnoraceae represents an independent origin of parasitism within the basal angiosperms, and that similarities with other holoparasitic groups have evolved convergently.

Balanophoraceae has about a hundred species in 17 genera, all of which are extremely reduced root holoparasites that have some of the smallest flowers in the world. Members of Balanophoraceae are found throughout the tropics and have broad host ranges but do not cause extensive crop damage. Balanophoraceae are sometimes included with the sandalwoods; however, molecular evidence does not support that relationship.

Cynomorium (Cynomoriaceae) is a holoparasite in the Mediterranean region comprised of two species that has sometimes been included within Balanophoraceae. As shown in **Figure 1**, Cynomoriaceae is not closely related to Balanophoraceae; instead it appears to be related to the order Sapindales, which includes the citrus family.

Krameriaceae includes 17 species of root hemiparasitic shrubs and herbs in the single genus *Krameria* that are often found in dry, open habitats in New World deserts and subtropics. *Krameria* species are unusual in that they produce floral oils that are used by oil-collecting bees. Traditionally, *Krameria* has been placed near the legumes (Fabaceae) or milkworts (Polygalaceae) due to a superficial resemblance of their flowers. Molecular evidence, however, unambiguously suggests a close relationship of Krameriaceae with Zygophyllaceae in spite of little morphological similarity between the two families.

Lennoaceae has two genera with five species of root holoparasites restricted to New World deserts in the southwestern United States, northwestern Mexico, and Columbia. All are herbaceous holoparasites of woody plants, including Boraginaceae (their closest known relatives) and Asteraceae. These strange parasites are spread by rhizomes often far beneath the sand or soil surface and are difficult to find unless flowering. *Pholisma sonora*, also known as sand food, was traditionally eaten by indigenous people.

Finally, one gymnosperm genus, *Parasitaxus* (Podocarpaceae), is parasitic on other free-living Podocarpaceae in New Caledonia.

Evolution of the Degree of Parasitism

The evolution of parasitism has been difficult to study because intermediate evolutionary stages between non-parasitic ancestor and extremely derived holoparasites are often missing. The variability in the degree of parasitism and the multiple origins of parasitism make these plants ideal for studying the evolutionary origins of parasitism and the often rapid canalization of parasitic traits. The degree of parasitism refers to

increases in the dependence that parasitic plants have on their hosts. Aspects of the degree of parasitism include the amount of carbon, water, or sugar obtained from the host, as well as major changes in the way that parasitic plants relate to a host. These major shifts include the evolution of stem parasitism or the evolution of an endophytic life history. The evolutionary factors that have influenced these events remain one of the most important questions about parasitic plants.

Changes in the degree of heterotrophy represents one of the most interesting and best-documented cases of quantitative evolution of parasitism. Some hemiparasitic root parasites and mistletoes are almost entirely autotrophic—that is, they obtain a small fraction of their carbohydrates from their host whereas holoparasitism (100% heterotrophic) occupies a presumably irreversible end-point of this quantitative scale. Most clades of parasitic plants are entirely hemiparasitic or entirely holoparasitic. Krameriaceae are all hemiparasites, while the Hydnoraceae, Rafflesiaceae, Apodanthaceae, Mitrastemonaceae, Cytinaceae, Lennoaceae, Cynomoriaceae, and Balanophoraceae are entirely holoparasitic. *Cassytha* and *Cuscuta* are often called holoparasites, although these species have very low amounts of chlorophyll. *Cassytha* species are yellow-green in color, while *Cuscuta* species are more orange-yellow. In *Cuscuta*, chloroplasts are less than 10% as numerous as in autotrophic plants but the green color is masked by yellow pigments.

Members of the order Santalales are mostly hemiparasitic, but at least one species represents a very advanced stage of parasitism. In *Arceuthobium*, the endophyte is extremely well developed and the leaves are reduced to scales. The most derived parasite in the Sandalwoods is found in the endophytic parasite, *Tristerix aphyllus*. *Tristerix aphyllus* is a parasite of columnar desert cacti, whose endophytic life history may allow the parasite to escape the hot and desiccating desert conditions. Curiously, *T. aphyllus* and all *Arceuthobium* species retain some chlorophyll, and in spite of these extreme advances toward parasitism, true holoparasites are absent in the order.

In contrast to the conditions in Santalales, within Orobanchaceae, holoparasitism has evolved on several occasions. In fact, some species include hemiparasitic and holoparasitic populations and the degree of heterotrophy varies substantially. Peter **Atsatt** (1970) was able to produce holoparasites in a few generations in artificial selection experiments. This suggests that the complete evolutionary loss of autotrophy, as seen repeatedly in Orobanchaceae, may be relatively common in nature. One obvious conclusion is that holoparasitism is more likely to evolve in root parasites than in stem parasites. Since root parasites are often found in the dark understory, the selective advantage of retaining functional chloroplasts in root parasites may be much weaker than for sunbathed stem parasites. In fact, holoparasitism in beech drops (*Epifagus virginiana*, Orobanchaceae) is clearly irreversible because entire sections of the genome that contain the genetic instructions for photosynthesis have been deleted.

The evolution of the mistletoe life history represents a different kind of innovation in the degree of parasitism that is different from the evolutionary loss of chlorophyll. Stem parasitism may have evolved more than once within the Sandalwoods; two families, Santalaceae and Loranthaceae,

have both stem and root parasites. It is possible that these represent paraphyletic taxa, but it is also possible that study of intermediates between root and stem parasites in Santalales will lead to an understanding of the evolutionary forces that led to the evolution of stem parasitism from root parasitism.

Parasitism and Other Phenomena in Plants

The utility of the strict botanical definition of parasitism is most apparent when parasitic-host interactions are compared with other plant-plant interactions. Almost all plant-plant interactions are characterized by conflict, and many are ecologically parasitic because one species exploits another. In short, each aspect of parasitism is present in another kind of plant-plant interaction.

Parasitic plants acquire resources directly from another plant. Similar phenomena exist in root-grafted forest trees and in mycorrhizal associations with fungi that indirectly connect plants. Root grafting is defined by a morphological continuum of the vascular tissue between two individuals that occurs in several species of forest trees. Interestingly, enough materials can be transferred through natural root grafts to sustain girdled trees. While root grafting is most common between closely related species, parasitic plants often form haustoria on a variety of species that are not closely related.

Mycorrhizal associations are very common in nature. Some mycorrhizal plants, such as indian pipe (*Monotropa*, Monotropaceae) have evolved complete heterotrophy and lost functional chloroplasts, much like holoparasites; actually these myco-heterotrophs are often confused for parasitic plants. In general, mycorrhizal associations are not species specific, and networks of mycelia and roots from a number of individuals can be interconnected thereby allowing the exchange of resources. In root grafts as well as mycorrhizal associations, source-sink relationships may exist between individuals; however, the precise relationship depends on ecological differences that may change over time. In haustorial parasitism, the parasitic plant is generally the sink while the host is the source.

Sometimes plants exploit the habitat created by another plant at the expense of the "host." For example, epiphytes use hosts primarily as anchors. Epiphytes intercept light, minerals, and water that might otherwise be available to the host plant. The reduction of available resources, plus the mechanical stresses on the supporting structure, may impose fitness costs on the host plant. A phenomenon related to epiphytism, but potentially more harmful to the "host," involves nurse-plant relationships, in which an established plant creates a microhabitat that facilitates the establishment of another species. For example, vines use the structural wood of trees to reach the forest canopy without investing in support themselves. In an extreme case, strangler figs twine around the trunk of a host, sending down adventitious roots to eventually support itself. Often the fig grows into a large tree that densely shades and envelops the host and may kill it. In contrast, parasitic plants impose fitness costs by removing water, mineral, and carbon resources from the host plant. They may also physically damage conducting tissues and negatively affect the host's metabolism through hormonal interactions.

Seed Dispersal, Germination, and Prehaustorial Events

Before forming haustoria, the seeds of a parasitic plant must germinate close to a host plant and make contact. Seeds have little control over where they are dispersed and because seedlings are fragile, encountering a host is an important but difficult challenge.

New contacts between hosts and root parasites are initiated by root growth; either the host grows near the parasite or the parasite grows toward the host. Some species use chemicals exuded by host roots as a cue for finding the host such that seedlings grow chemotropically up gradients. In facultative root parasites, the plants can invest in root systems that "search" for hosts. In the meantime, these roots can absorb resources and the plants can usually persist until they contact a host. In contrast, obligate parasites do not invest in elaborate structures; they must make contact immediately or die.

Seed size and number and the degree of parasitism are correlated in parasitic plants. Holoparasites generally produce large numbers of small seeds. This correlation is probably driven by different strategies for managing the risk of finding a host. Producing larger, more provisioned seeds allows the facultative parasite to persist until it finds a host, but the production of many small seeds increases the probability that at least some seeds will land near a susceptible host root. In general there is a negative correlation in all plants between seed size and number, which is thought to be related to resource limitations. Theoretically, resources are unlimited for parasites unless the host is killed. Therefore resource limitations may not be the reason for the seed size-number tradeoff in parasites.

In some species of obligate root parasites, seed dormancy may be prolonged as a way to spread the risks associated with finding a host over time as well as space. In other words, if a seed is dispersed to a suboptimal site, dormancy allows germination to occur at later times if the site becomes appropriate. Seed dormancy is broken when chemical cues indicate the proximity of a host. The first root exudate discovered to induce parasite seed germination was Strigol. This chemical is found in cotton and it stimulates the germination of *Striga* seeds. It is not known how well seeds discriminate between chemical cues of hosts from nonhosts in their local environment, but seeds often make mistakes. For example, cotton has been used as a way of managing *Striga* in agriculture by causing seed germination in the absence of a suitable host (see Parasitic Plants as Pests, below).

Mistletoe stem parasites must germinate on the stems of their hosts, requiring that seeds be dispersed directly onto a stem or leaf. Seeds are dispersed in two ways. Ballistic dispersal projects seeds up to 50 ft from the original host at velocities up to 90 ft/s as reported in *Arceuthobium*. Birds also disperse seeds of mistletoes over long distances because fruits are the main source of energy and protein for some birds. After consumption, seeds may be defecated onto hosts or the sticky seeds may attach to the bird's beak and be carried directly to another host. The seed may be wiped onto the host plant by the bird as it tries to remove the seeds from its beak.

The Haustorium

Haustoria are extremely varied structures among parasitic plants. In root parasites, haustoria are easily identified on exposed roots. They appear as swollen tissue at a contact point between parasite and host. In dodders, haustoria superficially resemble pegs or suction cups that connect the host and parasite. In general, haustorial cells occupy intercellular spaces and displace the host tissue, but enzymes also digest the host cell walls. Once a parasitic plant has encountered a host, it must penetrate the cambium and establish an interface. The interface is extremely varied. In most cases, the parasite forms a continuum with the xylem of the host plant, but in others (e.g., *Cuscuta*), the parasitic plant taps into the phloem. Host-derived materials may be transferred through strawlike intrusions into the host vascular tissue, or they are simply absorbed across cell walls. Haustorial cells near host tissue are usually rich in mitochondria and rough endoplasmic reticulum suggesting they are probably actively producing proteins that are likely used to produce digestive enzymes. After forming the initial haustorium, parasites may enhance local root growth to increase the number of haustoria and strength of the connection with the host. In stem parasitic mistletoes, seeds germinate and send out a radicle that grows into the host through a stomate.

The Physiology of Parasite–Host Interaction

Once a haustorium has established, the question remains: Why do materials move from host to parasite? Part of the answer appears to be quite simple for most xylem-tapping species: parasitic plants usually transpire at higher rates than their hosts to maintain a gradient in water potential across the haustorial boundary. The stomata of most plants close at night to conserve water, and they may also constrict during the day to reduce rates of transpiration under drought conditions. However, in many parasitic plants, stomata remain open at night, and they tend to maintain a high rate of transpiration throughout the day, even under drought conditions. Parasitic plants are among the least efficient plants at water use. In extreme cases, some species have glands to exude extra water. The net effect is that water and other dissolved substances move down the water potential gradient via mass flow from the host to the drier parasite.

If all the transfer of resources was facilitated in this manner, the concentration of nutrients should be higher in the parasite, but in the same proportion as the host plant. These general patterns are not found—instead, calcium generally has the same concentration as the host, while nitrogen, phosphorus, and potassium are enriched. Some evidence suggests that there is a component of active transport in parasitic plants. The haustorial cells at the interface have enhanced concentrations of mitochondria and show signs of being able to mobilize energy. It is possible that the main function of these cells is to pump unwanted materials back to the host. The potential benefits of reducing calcium concentrations and the mechanism(s) that make it possible are not fully understood.

The Ecological Advantages of Parasitism

In facultative parasites, the advantages of parasitism can be demonstrated experimentally. When grown with a host, parasitic plants look healthier, grow bigger, have more flowering branches, and produce more seeds. Compared with a patch of soil, the resources available in the vascular tissue of a host are extremely enriched. Parasitism allows plants access to a rich, hydroponic nutrient source. The benefit of parasitism can be mimicked experimentally by growing parasites in nutrient-rich solution culture.

A genus of annual hemiparasites, *Cordylanthus*, blooms during the hottest time of the year in an arid environment. Few other annual plants bloom at that time of year, and it is possible because the parasites use roots of perennial plants to gain access to groundwater. This unusual flowering time may also permit the parasites to have more exclusive access to pollinators.

In addition to nutrients and water, parasitic plants absorb secondary chemicals from hosts. Recent experiments by Michelle Marvier showed that herbivory is slowed and herbivores have lower fitness on parasitic plants that are attached to hosts that deter herbivory. Parasitic plants use a wide range of hosts, and, as a consequence, may accumulate a diverse and changing complement of protective secondary compounds. This strategy may effectively make parasites “moving targets” that are difficult for herbivores to “hit” in ecological or evolutionary time.

Host Specificity

In general, parasitic plants are considered to be host generalists. The advantage of this is quite simple; seeds can not choose where they are dispersed. Typically, a higher fraction of mistletoe seeds successfully establish on the species that is most abundant locally. In addition, dodders preferentially coil toward good hosts. Measuring host selectivity is much more difficult in root parasites than stem parasites. However, careful measurements by Gibson and Watkinson have demonstrated that root parasites are generally selective.

Some species are only found on one species or genus. The entire family, Rafflesiaceae, is composed of host specialists, as discussed earlier. Two closely related species of Orobanchaceae, *Epifagus virginiana* and *Conopholis americana*, are specialized on beech and oak trees, respectively. *Striga* (Orobanchaceae) tends to utilize grasses, and some species are highly host specific, even to the extent of requiring a particular subspecies as a host.

A tempting generalization is that species that are more dependent on their hosts tend to be more host specific. Kuijt rejected this hypothesis because most species of root holoparasites are host generalists. However, the most host specific species, including *Epifagus* and *Conopholis*, Rafflesiaceae, and *Tristerix aphyllus*, all represent extremely derived parasites. It may be that the endophytic lifestyle or the subterranean habit releases these plants from other selective pressures, and not that they become host specific because they are extremely derived. New phylogenetic evidence may provide more rigorous tests of this hypothesis.

Parasitic Plants as Pests

Many species of parasitic plants are economically important because they reduce crop yields. Parasitic plants remove nitrogen, phosphorus, and other mineral nutrients that may reduce the host's ability to grow. Parasitic plants have nutritional requirements that are very similar to their hosts, therefore the damage caused by a parasitic plant is often directly proportional to its biomass. In addition, parasitic plants are less efficient at water use than their hosts, so parasitized hosts will tend to be more water stressed than unparasitized hosts. Dodders do not have the same dramatic effects on water balance as mistletoes or root parasites, but their haustoria remove sugars and stunt developing fruits. In general, crops that are infested with parasitic plants grow slower, have lower yields, and are more susceptible to disease. In addition to crop plants, parasites are important pests of trees. The invasion of mistletoe haustoria into host trees can distort wood or alter growth patterns, thereby decreasing the value of the timber. Some mistletoes and dodders damage fruit trees or ornamental plants. The damage caused by these parasites is usually measured in lower yields, the loss of aesthetic value to ornamentals, or the increased effort required to control them. An enormous amount of research has focused on the root parasitic weeds, mistletoes, and dodders.

Root Parasitic Weeds

The most economically important root parasites are the witchweeds (*Striga*, Orobanchaceae). *Striga* includes approximately 17 species, of which, 11 are known to be pests. Most witchweeds have a tendency to parasitize grasses including sorghum, pearl millet, finger millet, rice, maize, and sugarcane. The most important witchweed species is *S. hermonthica*, which ranges from Ethiopia and Sudan through Sahel, north into Arabia, and south to the Ivory Coast, Nigeria, Angola, Namibia, and the Lake Victoria basin. *Striga asiatica* has a much wider range that includes much of Africa, parts of India, China, and Australia. In addition, *Striga asiatica* was accidentally introduced into North America in the 1950s. One species, *S. gesnerioides*, has very different host range from the other witchweeds; it uses a diverse set of broad-leaved hosts. It is best known for the damage it causes to cowpeas in West Africa, but it also damages tobacco in East Africa.

Among root parasites, the holoparasitic broomrapes (genus *Orobanche*, Orobanchaceae) are second to the witchweeds in terms of their economic impact. The geographical ranges of the economically important species are centered in the Middle East, but they are found further west and south into Africa, west and north into Europe, east into India, Pakistan, and Nepal, and north into Afghanistan, and several countries that were once in the Soviet Union. In general, broomrapes have wide host ranges. *Orobanche ramosa* attacks crops in Solanaceae, Brassicaceae, and Fabaceae. It sometimes attacks onions, but in general it is never found on grains (it was once reported on maize). The host range of *O. cernua* is more restricted; it parasitizes only Asteraceae (mainly sunflower) and Solanaceae (tobacco, tomato, and eggplant). *Orobanche crenata* Forsk. has a wide host range, but it is most

important as a pest of Fabaceae, especially faba beans and some Apiaceae (carrots).

The genus *Alectra* (Orobanchaceae) is closely related to the witchweeds. Of the 30 species, 4 are notable pests. *Alectra vogelii* and *A. picta* are pests of cowpeas and other pulse crops in semiarid Africa. *Alectra orobanchoides* occasionally attacks sunflowers or tobacco in South Africa and *A. fluminensis* parasitizes sugarcane in Central and South America. Several other genera in Orobanchaceae have agriculturally important species, but they are not nearly as important as the witchweeds, broomrapes, or *Alectra*. Other genera with notable or potentially important pest species include *Buchnera*, *Ramphicarpa*, *Odontites*, *Rhinanthus*, *Aeginetia*, *Melampyrum*, and *Christonia*.

Most control methods for root parasites focus on reducing host damage as well as seed set. Witchweeds and broomrapes produce hundreds of thousands of small, dust-like seeds per plant. Furthermore, the seeds can lie dormant in the soil for several years, and therefore reducing the size of the seed bank involves enormous effort. The most effective available method of control involves hand pulling the plants before they set seed. Although most of the damage to the host has been done by the time the parasitic plants emerge, hand pulling can reduce some of the damage. More important, early hand pulling prevents reseeding. If reproductively mature plants are pulled, care should be taken to prevent the seeds from being dispersed, and the adult plants should be burned.

More direct chemical methods can be used to reduce the seed bank. Ethylene gas, or artificial chemicals that mimic germination stimulants, can be applied to break dormancy and induce germination at times when no appropriate hosts are available. Alternatively, fumigants are applied to fields that kill seeds as well as other soil organisms. Raising the temperature of the soil by covering it with black plastic can also kill seeds.

Trap cropping, catch cropping, and crop rotation are other effective ways of managing the land. One option is to let the land lie fallow for 10 to 20 years to reduce the seed bank. This may not be an option where the demands on land use are heavy. Planting an unsuitable host is a more effective alternative that may allow the land to be used. Some alternative crops, called trap crops, induce seed germination but are not suitable hosts. A third option involves catch cropping. The land is seeded with susceptible hosts to induce germination of parasitic plants, but the crops are destroyed before the parasite can reproduce. Mixed cropping involves planting suitable and unsuitable hosts, and it has been demonstrated to reduce the impact of some witchweeds. The mechanisms, however, are not well understood.

Herbicides can also be used to control witchweeds. Herbicides applied directly to the soil after planting but before crop seedlings emerge can reduce or delay witchweed establishment. Systemic herbicides that are applied to the crop immediately after emergence may become translocated and concentrated in the parasites, killing them. The timing of application of systemic herbicides is critical because it must degrade before the crop begins to fruit. Some herbicides can be applied directly to the emerged witchweed to control them.

Damage to crops by witchweeds is minimized when nitrogen fertilizer is applied to host crops. This method has the added advantage of helping increase yields, but the benefits of

using this method alone over a long period of time have not been demonstrated. The mechanisms that allow nitrogen fertilization to decrease the impact of the parasitic plants are not fully understood. It does seem clear, however, that on poor soils, the witchweed infestations increase in intensity as the quality of the soil decreases; the result is a feedback that continues until the land is almost useless and must be abandoned.

One of the most promising control options is the development of resistant varieties of crop plants through plant breeding. As new resistant varieties are found other methods of control become unnecessary. Resistant varieties of many crops have not been discovered, however, therefore this is a very active area of research.

Parasitic plants may pose the largest problem to rural, subsistence farmers. As pressures on land use increase, the ability to use crop rotation methods decreases. Furthermore, subsistence farmers often do not have the means to buy fertilizers, herbicides, or expensive resistant seeds. For these farmers, the feedbacks between poor soils and parasitic plant infestation may eventually cause the farmers to abandon plots of land and move elsewhere.

Mistletoes

Several species of mistletoes are economically important pests of fruit trees, ornamental trees, or timber. Most mistletoes have a similar ecology, so the impact and control measures are easy to generalize. The exceptions are dwarf mistletoes (genus *Arceuthobium*, Viscaceae) that have a much more highly developed endophytic component and inconspicuous, scaly leaves. Because of the highly developed endophyte, physical removal of dwarf mistletoes is more difficult than other mistletoes.

Most species of dwarf mistletoes are extremely host specific. For example, *A. douglasii* is a parasite of Douglas fir, and *A. tsugense* is a parasite of the western hemlock. The dwarf mistletoes are parasites of pine trees in North America, the Himalayas of India, Pakistan, and Bhutan, and in southwestern China. Dwarf mistletoes are common throughout the Rocky Mountains where large regions of forests are infested and the timber volume and quality are affected.

Two other genera in Viscaceae are notable for their economic impact. *Phoradendron* is a genus of about 190 species distributed throughout North and South America. Of these, the most important are *P. serotinum*, found on an extremely wide variety of hosts (but never conifers), and *P. piperoides*, found on cocoa in Costa Rica. *Viscum* is a genus of about 60 species that include *V. album* that has an extremely wide host range including fruit trees, pines, and poplars in Europe and persimmon in China. Another agricultural pest is *V. cruciatum* that parasitizes olives in the Middle East.

Many species of Loranthaceae cause economically significant loss. *Dendrophthoe falcata* is a pest of fruit trees in India and teak in Kerala. *Dendrophthoe pentandra* parasitizes rubber and kapok in Indonesia. *Helixanthera mannii* is a pest of citrus and coffee in West Africa, and *H. parasitica* is a pest of citrus in the Himalayas. *Tapinanthus bangwensis* is an important pest of cocoa and cola in Ghana, while *T. globiferus* grows on coffee, citrus, and other fruit trees in Ethiopia. Some other genera that have economically important species are *Amyema*,

Englerina, *Loranthus*, *Macrosolen*, *Oryctanthus*, *Phragmanthrea*, *Scurrula*, and *Struthanthus*.

Some resistant varieties of poplars, pines, and oaks do exist, but very little variability for resistance to mistletoe infections exists and, in general, breeding for resistance has not been a viable option. Biological control by insects, pathogens, or other mistletoes remains a possibility, but none of these methods have been successful. Instead, control of the leafy mistletoes involves pruning off infected limbs, or chemical control. Pruning infected limbs removes the mistletoe, but the limb must be cut below the point of the infection to remove the entire endophyte. This practice is extremely labor intensive and impractical on a large scale. With *Arceuthobium*, the endophyte is often extensive, and the limb must be severed 20 to 30 cm below the lowest parasite shoots. In extreme cases, it may be more cost-effective to burn the forest. In less extreme cases, early harvest followed by controlled burns may reduce the mistletoes. Some successful chemical control methods have been found. The leaves of mistletoes may be sprayed with ethephon once the host drops its leaves. Alternatively, herbicides can be injected into infected limbs below the point of infection, accumulate in mistletoes, and eventually kill them without severely affecting the host.

Dodders

The economic impact of *Cuscuta* species is greatest in forage crops such as alfalfa and clover; however, crops like citrus, coffee, peach, litchi, flax, linseed, and other crops as well as ornamental plants all suffer from dodder attack. The most economically important dodder is *Cuscuta campestris*. This species attacks alfalfa and has been shown to reduce forage yield by as much as 57% over a 2-year period. It also affects Niger seed in India and many vegetable and flower crops. Of the 20 species of *Cassytha*, the most damaging is *C. filiformis*. It is distributed throughout the tropics and parasitizes a wide range of hosts. It is a problem on citrus in India and Tanzania and on *Pinus massonia* in China.

Mechanical control methods for *Cuscuta* include hand pulling, crop rotation, burning, delaying planting until after *Cuscuta* have germinated, or deep ploughing to reduce the seed bank. Few resistant varieties of crops are known. Chemical control methods include fumigants to eliminate the seed bank, herbicides applied to the soil to prevent seedling growth, and herbicide application after seeds have germinated to prevent establishment. Some methods of biological control have been established with insects and pathogens, but the scope of these has been limited.

Conclusions

Parasitic plants have been understudied, but recent studies have improved our understanding of their evolution, ecology, molecular biology, and physiology. Haustorial parasitism has evolved independently at least 12 times within angiosperms and, surprisingly, complete loss of photosynthesis has occurred multiple times within some lineages. Most parasitic plants exhibit near-normal levels of photosynthesis like their

autotrophic ancestors, whereas others are incapable of photosynthesis such as the derived endophytic holoparasites. Study of parasites that photosynthesize at intermediate levels will be important to understand the evolution of holoparasitism. Development of sophisticated molecular methods will be important for understanding the bases of haustorial development and should ultimately enhance efforts to control economically important crop pests. Further ecological and physiological studies aimed at understanding host-parasite interactions will also enhance efforts to control parasitic weeds.

Acknowledgments

We thank the NSF (grants DEB-91029258, DBI-9604814, and DEB-9811362 to C. W. D.) for funding our research on parasitic plants, and Joel McNeal for critical reading of the manuscript. Other important contributions of data, samples, or discussion, were also made by other members and friends of the dePamphilis lab, past and present, and by numerous botanical gardens and botanists with an interest in parasitic plants.

Glossary

Acid deposition Anthropogenic acidification of terrestrial and freshwater ecosystems by (primarily) sulfuric acid, derived from sulfur dioxide produced by burning oil and coal and deposited in rain and snow (acid rain), directly as particles (dry deposition) and as cloud droplets.

All taxa biodiversity inventory (ATBI) The idea, first suggested by D. H. Janzen, that it might be feasible to produce a complete species list for all the organisms living in one place, a hectare of tropical forest, for example. The goal has so far proved elusive.

Bioassay The use of living cells or organisms to make quantitative or qualitative measurements of the amounts or activity of substances.

Community An assemblage of species populations that occur together in space and time.

Ecotoxicology The use of test organisms (e.g., the water flea, *Daphnia*) to study the toxicity, pathways of accumulation, and breakdown of chemicals, particularly those manufactured by humans (e.g., pesticides).

Endemic species Species confined in their distribution to a particular geographic region. The size of the region is arbitrary (a species can be endemic to North America or to a tiny island).

Hot spots A word with several distinct meanings. Here it is used to denote sites unusually rich in a particular group of species (e.g., birds), compared with average sites in the same geographic region. (The converse is a “cold spot.”) Has also been used to denote centers of endemism (*see* Endemic Species), which need not be unusually species rich; it is not used in this context here.

Paleoclimatology The study of past climates from fossils and other traces left in the geological record.

Reserve selection algorithms Mathematical techniques used to maximize efficiency in the selection of protected areas for conservation. The efficiency criteria vary with circumstances but may, for example, be the minimum number of reserves with every species represented, or minimum cost.

Species as Indicators of the State of the Environment

There are three distinct uses of the term “indicator species” in research in ecology and biodiversity. They are a species, or group of species, that do the following:

1. Reflect the biotic or abiotic state of an environment.
2. Reveal evidence for, or the impacts of, environmental change.
3. Indicate the diversity of other species, taxa, or entire communities within an area.

This article explains, provides examples of, and evaluates each of these uses of the term, focusing primarily on terrestrial and freshwater ecosystems; broadly similar conclusions apply to marine ecosystems, but marine examples lie beyond the scope of the article. We pay most attention to the third use of the term “indicator species,” because this seems most appropriate for an encyclopedia devoted to biodiversity. The most up-to-date evaluation and review of indicator species in the scientific literature is by McGeoch (1998). She concentrates on terrestrial insects as “bioindicators” (in all three senses of the word) but the general principles that she discusses extend to all ecosystems and organisms, not just to terrestrial insects.

Everybody knows that living organisms are sensitive to the state of their environment. Pollution from human activities kills many species and reduces the abundance of others. These

changes in abundance can be used to assay the state of the environment.

An Example: Acid Deposition

Sulfur dioxide, produced by burning fossil fuel, particularly coal, enters the atmosphere and is eventually deposited on terrestrial and freshwater ecosystems via three routes: (a) as tiny solid particles, (b) washed from the air in rain or snow, or (c) as droplets formed in clouds. Deposition often occurs hundreds of kilometers from the source. Dissolved in water, sulfur dioxide forms sulfuric acid, resulting in what is frequently referred to as “acid rain,” but because there are three principal routes involved in its transfer to terrestrial and freshwater ecosystems, it is more correctly called “acid deposition” (Erisman and Draaijers, 1995). Sulfur dioxide is not the only source of acidification; oxides of nitrogen, again produced by burning fossil fuel, are also involved, but sulfur dioxide is the main agent of acidification in most ecosystems.

In terrestrial ecosystems, this deposition kills lichens and acidifies the soil, leading to changes in the vegetation. Lakes become progressively more acidic as deposition loads increase, until eventually they may become virtually lifeless. A trained biologist, visiting for the first time an area subject to acid deposition, will often be able to deduce that the habitat is being polluted simply by looking at the species that are present and those that ought to be there but are not. Beautifully

clear Scandinavian lakes, lacking any fish or amphibians, supporting few birds and a species-poor and taxonomically unusual invertebrate fauna, have been reduced to this impoverished state by the transnational export of sulfur dioxide from coal-burning power-stations in the United Kingdom and elsewhere in Europe. Here, living organisms act as powerful indicators of the state of the environment and the damage being done to it by human activities, often performed many hundreds of kilometers away.

Management of European Rivers

Because the species composition and richness of biological communities change as the environment changes, we can use species as indicators of the state of the environment for practical management purposes. The techniques have been particularly well developed to assess organic and inorganic pollution in European rivers, managed for recreation, fisheries, and drinking water. The advantages of using living organisms as indicators of water quality are that they avoid the need for expensive chemical analyses, and, probably more important, organisms integrate the impacts of pollutants over space and time. All chemical traces of a major pollution incident may disappear from a river in a matter of hours as the pollution is flushed from the system. Nonetheless, the biotic community may show evidence of the damage for many months. It is extremely difficult, and prohibitively expensive, for chemists to measure all the organic and inorganic chemical pollutants entering a river, and it is certainly impossible for them to work out what all the combined impacts of such a cocktail might be. But living communities reflect the integrated effects of all the compounds that find their way deliberately and accidentally into watercourses, and hence they act as sensitive indicators of the state of the environment. A valuable source of further information on the use of living organisms to monitor the environmental health of rivers and lakes is provided by [Rosenberg and Resh \(1993\)](#).

Two widely used European examples of this approach are the German Saprobic Index, and RIVPACS in the United Kingdom. RIVPACS is now used by the Environment Agency to manage UK rivers. Both the German and UK approaches require accurately identified samples to be taken of the organisms found along sections of the river. RIVPACS focuses on invertebrates, the German index on invertebrates, microbes, and higher plants. Both rely on the fact that some species are extremely tolerant of pollution (the aquatic larvae of some chironomid midges, for instance), while others are extremely sensitive, particularly to the low oxygen levels produced by organic pollution (for instance, the larvae of many mayflies). The species present in the samples are given scores, depending on their known tolerances, and the data from all species are combined to produce a composite and very sensitive index of pollution levels for any particular section of a river.

Widespread Application

Use of organisms to indicate the state of the environment is widespread, taxonomically and geographically, for a wide range of environmental issues. Use of species as indicators of

the state of the environment is not confined to freshwater, or to Europe and North America. A wide variety of organisms has been suggested, or used, as indicators of human impacts. In Europe, suites of plant, fungal, and insect species are only found in, and hence are good indicators of, ancient woodland; they are entirely absent from plantations, even though these may be several hundred years old. The use of lichens as sensitive indicators of air pollution is well known, but organisms as different as mites and geckos (agile, climbing lizards) have been used, or suggested, for similar purposes. Lichens have also been used as indicators of fire history in Brazilian *cerado* (a type of dry, scrubby forest), tiger beetles as indicators of tropical forest degradation in Venezuela, and day-flying Lepidoptera (butterflies and moths) as indicators of the state of seminatural grasslands for conservation in Europe. Many other similar examples exist.

Interpretation Requires Care

In these and similar cases, considerable care is needed before a species or group of species can be used as reliable indicators of damaging (or beneficial) human impacts on ecosystems. All populations of living organisms fluctuate over time and vary in abundance spatially, because of natural variations in the weather, normal changes in the physical environment, and fluctuations in the abundances of natural enemies, competitors, and essential resources (food and shelter). Just because one or more species is declining does not mean that human impacts are to blame. In the case of lichens and atmospheric pollution or freshwater invertebrates and river quality, the links between anthropogenic pollutants and changes in the distributions and abundances of organisms are thoroughly researched and well understood. But even quite major declines in some species have proved exceptionally difficult to link to damage to the environment caused by people.

Amphibian Decline

The so-called amphibian decline is a particularly dramatic example ([Blaustein and Wake, 1995](#)). In many parts of the world, population biologists interested in amphibians (frogs, toads, newts, salamanders, etc.) have recently become alarmed by apparent major declines in the abundance, and the complete disappearance, of many species from areas where formerly they were common, often in regions apparently remote from human impacts. The declines are not happening everywhere, and the magnitude of many of those that have been claimed is difficult to assess because of the lack of long-term data prior to the supposed population collapses; some of them may be perfectly natural. The worrying aspects of the phenomenon are that while it is apparently global in scope, the causal mechanism (or mechanisms) remains obscure. It has been suggested, for example, that the amphibian decline is indicative of rising global levels of damaging ultraviolet light (UV-B) caused by loss of the earth's protective stratospheric ozone layer. Amphibian eggs, exposed in shallow water, and the adults with their thin wet skins may be particularly sensitive to UV-B, as are human sunbathers without sunblock.

Others doubt the explanation. More recently a global pandemic has been implicated. But what should suddenly trigger lethal outbreaks of disease in amphibians is unclear.

Environmental Toxicology

In all the examples so far, the organisms being used as actual or possible indicators of environmental health have been in their natural environment. There is another related but quite separate way in which biologists use the sensitivity of organisms to set environmental standards, namely in the science of environmental toxicology, or ecotoxicology for short. In many areas of human endeavor, the aim is to apply some beneficial technology with minimum environmental damage. Crop spraying with pesticides is a good example, and so is the discharge of treated effluent from a factory. Some environmentalists claim that these types of operations should not lead to any environmental contamination; factories should have zero discharges, and if we must use pesticides, they should be targeted to reach only the crop and the pest and not, for example, the soil, nontarget organisms, or adjacent watercourses.

However, zero discharges or precision pesticides, if they can be achieved at all, can often only be obtained at great economic cost. The more pragmatic solution is to ask whether there are minimal levels of discharge, spray drift into watercourses, and so forth that cause no detectable environmental damage. To provide answers to this admittedly difficult question, environmental toxicologists use a wide variety of laboratory bioassays with standard organisms. Examples from freshwater include the alga, *Chlorella vulgaris*, the water flea, *Daphnia magna*, the amphipod shrimp, *Gammarus pulex*, and the rainbow trout, *Salmo gairdneri*. The fundamental problem is to try and establish acceptable levels of contamination. Defining “acceptable” obviously requires political as well as biological judgment. However, traces of a compound in water, air, or soil that cause no detectable changes in the performance (growth, survival, or reproduction) of the test organisms are clearly more acceptable than doses that kill 50% of the population (so called LD₅₀ levels). Basically, the bioassays seek to set environmental standards for levels of potential pollutants in soil, air, and freshwater, using a range of standard laboratory organisms as indicators (Shaw and Chadwick, 1998), but there can be no absolute standards about what is safe or acceptable. The general trend in modern societies is for standards to gradually tighten.

Species as Indicators of Environmental Change

If the amphibian decline (discussed in the previous section) is real, it is an example of a group of organisms acting as indicators not only of the state of the environment, but also as indicators of ongoing changes to the global environment, albeit of an unknown nature. In other words, given that species are sensitive to the condition of their environment, monitoring organisms not only tells you about the current state of an environment, but *repeated* monitoring can tell you about *changes* in that environment. To act as indicators of change rather than current environmental health, it is necessary to

have at least two sets of data on the particular indicator species in question, taken in the same way, at the same place(s), on two separate occasions. More frequent sampling allows greater confidence in the direction of apparent trends and the detection of more subtle environmental changes.

Not all Monitoring is about Environmental Degradation

Not all monitoring of species seeks to record environmental degradation. Increasingly after mining operations, for example, mine operators are required to restore spoil heaps and mine pits by sowing or planting native vegetation. Monitoring selected groups of common animals on nearby undisturbed control sites and on the restored land can give a good indication of the recovery of the entire ecosystem and of the success of the restoration project. For instance, when biologists monitored ant assemblages on abandoned, replanted bauxite mines in Australia, they found that the ants provided a good indication of the recovery of these ecosystems. Even after 14 years there were still differences between the ant communities found in the natural *Eucalyptus* forest and the restored land.

Historical Records of Change

Lake Acidification

It may not always be necessary to sample in real time. When anthropogenic acidification of lakes was first discovered, many people doubted that the phenomenon was real. In particular, there was considerable opposition to the notion from the power-generating industry, because solving the problem (by burning low-sulfur coal, adding “scrubbers” to power station chimneys to remove sulfur dioxide, or switching to natural gas) was inevitably going to be expensive. After all, there were few historic data on the state of the acidified lakes. Perhaps they had always been that way?

Resolving the problem required knowledge of the fact that lake phytoplankton (the tiny, unicellular plants that float in the upper layers of lakes) are extremely sensitive environmental indicators, because different species grow best in very different conditions determined by nutrient status and pH (acidity). When algae die, they sink to the bottom where their bodies and characteristic pigments are buried and some are preserved (incipient fossils), particularly the resistant, silicious outer cases of a group called diatoms. An undisturbed core through the sediments records the history of a lake’s phytoplankton, with the oldest flora at the bottom. Cores showed unequivocally that many Scandinavian lakes that are acid now were not acid before the Industrial Revolution; the oldest diatoms—species not found in acid lakes—are gradually replaced in the sample column by acid-tolerant species. Diatoms are wonderfully sensitive indicators of environmental change (Figure 1).

Plants and Carbon Dioxide

Herbarium specimens (pressed plants collected for taxonomic purposes) and fossil leaves can also be used as indicators of past environmental change. Another consequence of the rapid rise in the burning of fossil fuel since the Industrial Revolution has been an accelerating rise in the concentration

Figure 1 The pH history of Lilla Öresjön, a 0.6 km² lake in southwest Sweden. A core of the bottom sediments 3.5 m long records the history of the lake extending back to 12600 BP, using the valves (“shells”) of diatoms preserved in the deposits. Different species of diatoms have different pH preferences and can be classified accordingly. Acidobiontic species thrive in acid waters; alkaliphilous species prefer more alkaline conditions. Combining data from the remains of all species of diatoms allows the pH history of the lake to be reconstructed. The lake has passed through four pH periods. A, an alkaline period after deglaciation. B, a naturally more acidic period. C, a period with higher pH, which started at the same time as agricultural expansion in the region, and D, a rapid, recent period of acidification. The post-1960 phase has no similarity with any of the previous periods. Reproduced from Renberg I (1990) *Phil Trans. R. Soc. London B* 327: 357–361, with permission from Royal Society of Publishing.

of atmospheric carbon dioxide, one of the main agents of “global warming.” We will deal with species as indicators of anthropogenic global climate change (as it is more accurately known) later. Here we want to focus on physiological and developmental responses within single species to rising carbon dioxide.

If plants are grown in a greenhouse under different atmospheric carbon dioxide concentrations, from below the pre-Industrial Revolution levels of about 280 parts per million by volume (ppm), through what are roughly present levels of 350 ppm, to levels that may be reached by the end of the 21st century (700 ppm), several interesting things happen. In particular, in the present context, stomatal densities on the undersides of the leaves decline. Stomata are the tiny pores in the leaf surface through which plants take up carbon dioxide (needed for photosynthesis), and through which they lose water vapor. It has been known for a long time that plants control the opening and closing of stomata to optimize carbon dioxide uptake and reduce water loss. More surprising, we now also know that plants grown in high carbon dioxide have lower densities of stomata; something happens during leaf development to reduce the number of stomata. How and what is currently unclear. Why is simple enough. In a high carbon dioxide world, the plant needs fewer stomata to take up the carbon dioxide it requires and hence can satisfy the needs of photosynthesis and reduce water loss by developing fewer pores in the leaves.

Now back to those herbarium specimens and fossil leaves. If you look at 200-year-old (and very precious) herbarium and modern specimens of the same species, sure enough, stomatal densities decline as global atmospheric carbon dioxide levels increase (Figure 2A). The same approach has recently been used to try and trace atmospheric carbon dioxide levels

throughout most of the Phanerozoic, from the time when plants first colonized the land. Here the method is more contentious, because different species of truly fossil plants with presumed similar growth forms have to be used in different geological periods. Nevertheless, the pattern of apparent changes in global atmospheric carbon dioxide concentrations over hundreds of millions of years, revealed by this method (Figure 2B and C), are in reasonable agreement with alternative, independent, and also contentious geochemical methods. Here is a really unusual use of species as indicators of environmental change.

Species as Indicators of Climate Change

The Sensitivity of Species to Climate: Fossils Again

Current, rapidly rising concentrations of atmospheric carbon dioxide are the primary cause of anthropogenic global climate change. However, the earth’s climate has always changed, naturally, with no intervention from human beings. One of the ways we know this is through the careful documentation of the types and distributions of organisms in the fossil and subfossil record. The science of paleoclimatology, which seeks to reconstruct the history of earth’s climate, relies heavily on changes in fossil and subfossil species assemblages to deduce what the earth’s climate was like thousands or even millions of years ago. To take one example, in the modern world many types of corals occur exclusively in tropical marine environments; it is a winning bet that fossil corals of the same type indicate an ancient tropical sea, even though the rocks bearing the fossils may now lie in much colder parts of the world.

In more recent geological time, we can use changes in the distributions and abundances of plants and animals to trace

Figure 2 Changes in stomatal densities of leaves as indicators of changes in atmospheric carbon dioxide concentrations. (A) Percentage changes in stomatal densities on the lower surfaces of the leaves from eight species of trees and shrubs collected from the English midlands and preserved as herbarium specimens. The oldest specimen was collected in 1750. As atmospheric CO₂ has risen during and since the industrial revolution, so stomatal densities have fallen. (B, C) Assuming that similar effects occur in all species of plants, fossil leaves can be used as indicators of atmospheric CO₂ concentrations extending back many millions of years. The CO₂ content of the earth's atmosphere appears to have fluctuated markedly and apparently naturally during the past 400 million years. Reproduced from Beerling DJ and Woodward FI (1997) *Bot. J. Linn. Soc.* 124: 137–153, with permission from Wiley.

major changes in the earth's climate during the Holocene (the most recent geological past) and Pleistocene glacial and interglacials. Plant remains preserved in packrat middens in dry air of the southeastern United States attest a much wetter climate only a few thousand years ago. Hippopotamus bones and teeth dug up from under Trafalgar Square provide unequivocal evidence of a much warmer London. Pollen grains preserved in peats and lake sediments record in exquisite detail the march northward of European and North American forests from the end of the last glaciation 12,000 years ago (Huntley and Birks, 1983). The forests spread with remarkable speed (an average of about 200 m per year, but sometimes as fast as 2 km a year) to achieve present distributions in the northern parts of both continents from glacial refugia thousands of kilometres to the south (Figure 3A and B). The information is not won easily. It requires huge patience and great skill to identify thousands upon thousands of pollen grains extracted onto microscope slides. But once done, the record reads like a speeded-up movie, as spruce, oaks, white

pine, hemlock, beech, and chestnut swept north in successive waves through what is now the United States and Canada; in the more species-poor forests of Europe, pines were followed by birch, then oak. These invasions are as dramatic as any in human history, but they were silent and recorded only by pollen grains.

Contemporary Changes in Species Distributions

Historical changes aside, there is now no doubt that the world is currently warming quite rapidly. An upward trend in global annual mean surface temperatures is apparent from about 1920, particularly over the last two decades (from c. 1980); global mean surface temperatures in July 1998 were the highest ever recorded. Do organisms act as indicators of these changes, perhaps, as with the freshwater species discussed earlier, acting subtly to integrate several of the changes humans find difficult to comprehend in the bald statistics? Climate change does not simply involve warming; it involves changes in rainfall, extreme weather events (droughts and

Figure 3 The migration of trees across North America and Europe after the end of the last glaciation, revealed by pollen remains in lake sediments and peat. (A) The spread of oaks in North America, with radiocarbon ages in thousands of years (contours) and the present range of the genus (shaded). (B) Estimates of the overall rates of spread of trees on two continents, based on data of the type shown in part A. Reproduced from Williamson M (1996) *Biological Invasions*. London: Chapman & Hall.

storms), and even locally cooler conditions. All these complex changes should show up in changes in the distributions and abundances of organisms.

They do. Species are proving to be extremely sensitive indicators of contemporary climate change, where historical records allow decent reconstruction of former and current distributions. Populations of Edith's checkerspot butterfly *Euphydryas editha* are disappearing from southern California and northern Mexico, at the current southern end of its distribution, and from more lowland sites; sites where previously recorded populations still exist are on average 2° further north than sites where populations went extinct (Figure 4). These are exactly the changes we would expect in a warming world. Twenty years ago in northwest Europe, little egrets *Egretta garzetta* (small white herons) used to be rare visitors from the Mediterranean. Now they are breeding in northern France and southern England in an astonishing expansion of range. Populations of many other European birds, butterflies, and other organisms are spreading north at the present time, as the climate warms.

Of course, none of this tells us whether the climate change that is certainly happening is "natural"—it could have happened anyway and may have nothing to do with anthropogenically produced greenhouse gasses—or whether it is indeed due to human activities. Using species as indicators of climate change tells us unequivocally that the earth's climate is changing, but so does the mercury in the thermometer. What

neither tells us is why, and no end of work on species as indicators will solve that dilemma. As we have already seen, this situation is not unique to climate change. It generally holds whenever we use species as indicators of the state of the environment. Indicator species can tell us whether an environment is, or is not, changing. They do not tell us why the changes are taking place. That almost always requires additional detective work, although knowledge of an organism's biology will frequently provide valuable clues. Three examples, using birds as indicators, illustrate the problem in more detail.

Birds as Indicators of Large-Scale Environmental Changes

Birds are widely used indicators, because in Europe, North America, and other parts of the world where there are large armies of amateur bird watchers their populations and distributions have been recorded well enough, for long enough, to reveal major environmental trends.

Peregrine Falcons and DDT

The catastrophic collapse of peregrine falcon *Falco peregrinus* populations throughout the northern hemisphere in the 1950s signaled widespread contamination of the environment by chlorinated hydrocarbon insecticides, first DDT, then other compounds such as aldrin and dieldrin. The total, and rapid, disappearance of these dramatic birds signaled to

Figure 4 The fate of 151 previously recorded populations of Edith's checkerspot butterfly, *Euphydryas editha*, in western North America. The populations ranged from northern Mexico to southern Canada and were visited by Camille Parmisan and other biologists between 1992 and 1996. Populations that had disappeared because of habitat degradation (e.g., loss of usable host plants) were omitted from the analysis. Dividing the populations into five, evenly spaced latitudinal bands between 30° N and 53° N (A) reveals that significantly more southern populations have gone extinct than northern populations; sites where previously recorded populations still exist were, on average, 2° further north than sites where populations were extinct. Extinctions were also higher at lower altitudes (B) (*n* is the number of populations in each latitudinal or altitudinal band). Both results are consistent with the effects of global climate warming on the butterfly, leading to a northward and upward shift in its geographical range. Reproduced with the permission of McMillan Journals Ltd, from *Nature* **282** (1996), page 766.

ornithologists that something was seriously wrong with the environment, but what? It took a great deal of clever biological detective work (see Ratcliffe, 1980) to link the decline of peregrine populations to the accumulation of these persistent

pesticides up the food chain, resulting in eggshell thinning, reproductive failure, and (in extreme cases) direct poisoning of adult birds. Although some populations have now recovered, signaling a recovery in environmental quality, the species is still missing from many parts of its former range—some coastal populations in England, for instance. Nobody knows why.

Migratory Songbird Declines in North America

In North America, considerable concern is currently being expressed over widespread declines in summer migrant birds, particularly warblers. Unlike the so-called amphibian decline, nobody questions the phenomenon; just like the amphibian decline, nobody really knows why it is happening. There is no doubting the data; many species are indeed declining very quickly, in as clear an indication as one wants that something is wrong with the environment, but what? Several possibilities exist, and they are unlikely to be mutually exclusive. One explanation focuses on the destruction of tropical forests in the birds' wintering areas. Another suggestion is that there are other unknown problems there or on the migration routes. A third possibility is extensive habitat fragmentation and urbanization in the breeding forests of the eastern seaboard. This human modification of the northeast forests markedly increases nest losses of migrant songbirds to jays, crows, cowbirds, and racoons, all species that thrive in the slipstream of urban humans.

Declines in Formerly Common Farmland Birds in Northwest Europe

In the intensively agricultural areas of northwest Europe—over the whole of lowland England, for example—a whole raft of formerly “common farmland birds” are also in steep decline (Tucker and Heath, 1994). They include skylarks (*Alauda arvensis*), European tree sparrows (*Passer montanus*), corn buntings (*Miliaria calaudra*), gray partridges (*Perdix perdix*), and song thrushes (*Turdus philomelos*). Here the problem is now reasonably well understood, though many details remain unresolved. Modern farming is so efficient and clean that there is little for the birds to eat. Weeds are killed with herbicides, which remove both seeds and rich sources of insects that feed on the weeds. The crop itself is sprayed to remove insects and is harvested so efficiently that few seeds are spilled on the way. Modern farms are biodiversity deserts, an indication of the power of people to squeeze nature to the margins while apparently maintaining a green and pleasant land. If present trends continue, skylarks will be rare birds in Britain in 20 years.

Species as Indicators of Biodiversity

The Nature of the Problem

Common sense suggests that the known losses of plants and birds from European farmland will go hand-in-hand with much more poorly documented declines in many other, less familiar and cryptic taxa, from land snails to glowworms, and hoverflies to harvest spiders. In other words, changes in the distribution and abundance of well-known groups should

serve as broad indicators of the status of, and changes in, a much wider sample of a region's flora and fauna. The assumption here is that birds (or other conspicuous species) might serve as biodiversity indicators—that is, as surrogates of overall biodiversity. But although it seems intuitively reasonable to use familiar, well-studied, and easily censused groups as indicators of what is happening to many other taxa, despite a great deal of research, the idea is actually contentious.

Following (but slightly modifying) the work of McGeoch (1998), we can define a biodiversity indicator as a group of taxa (e.g., genus, tribe, family, or order, or a selected group of species from a range of higher taxa) whose diversity (e.g., overall species richness, number of rare species, levels of endemism) reflects that of other higher taxa in a habitat, group of habitats, or geographic region. The idea is simple enough, and if it can be shown to work, it is important because biologists then have a relatively simple means of assessing overall biodiversity for purely scientific reasons, for setting conservation priorities, or for monitoring the effectiveness of conservation management.

Taxa that have been Suggested as Indicators of Biodiversity

The groups of organisms whose richness has been evaluated most thoroughly in the greatest number of places on earth are also the most familiar. The natural history sections of bookshops are dominated (sometimes exclusively) by volumes on plants and birds. If insects figure at all, butterflies will be on the top of the list, although there are fascinating differences between nations. Japan loves dragonflies. Birds, higher plants, butterflies, and dragonflies are all groups that occur in most places in the world but whose individual species are seldom so widespread. In much of the world they are also groups whose species are, relatively speaking, taxonomically well known and stable, readily identifiable, and have biologies that are well understood. They are easy to find, inventory, and count, and they are reasonably, but not overwhelmingly, diverse in any one place. These are all desirable attributes of groups that might be used as indicators of the diversity of many other, much less well known taxa—that is, as indicators of the overall biodiversity of a region.

Other groups have many of these same attributes but have not gained the same popularity, perhaps because often they are not also large bodied or perceived as being quite so attractive. The list of those that have been advocated as useful biodiversity indicators at one time or another is very long. It includes soil nematodes, moths, beetles galore (tiger, carabid, dung, and buprestid, to name but four), termites, fish, frogs, and snakes. Whatever the group, they must also have one further attribute—namely, that they genuinely indicate levels of biodiversity or at least some of the components of primary interest. The fact that the scientific literature contains suggestions for so many different possible indicators shows that there is little consensus on the matter. Many have been called, but few are chosen. Why? There are two, related, reasons. First, scientific knowledge on the degree of coincidence in patterns of biodiversity between

different taxa is surprisingly poor. Second, as knowledge improves, coincidence between many taxa turns out to be much worse than people had imagined, or indeed hoped, would be the case.

Knowledge is Poor Because of the Effort Required

Gathering information on the diversity of different groups of organisms, even in one place, is enormously time-consuming. Two examples illustrate the problem. To map the presence and absence of breeding birds (conspicuous, “easy” to find and to identify) in every 10×10 km grid-square in Britain and Ireland (there are 3672 squares) took more than half a million individual record cards, filled in by an army of amateur bird-watchers coordinated by professional ornithologists in the British Trust for Ornithology (BTO). The task took 4 years and about 100,000 hours of fieldwork (Gibbons *et al.*, 1993). Now imagine the effort required to do the same thing for all the other hundreds of different groups of organisms found in this one small corner of Europe. It has been done for a sample of taxa (we will return to what these data show in a moment), but many groups remain unmapped.

At a much smaller spatial scale in a tropical forest in Cameroon, a group of biologists attempted to measure the impacts of forest disturbance on just eight groups (birds, butterflies, flying beetles, canopy beetles, canopy ants, leaf-litter ants, termites, and soil nematodes). The birds and the butterflies took 50 and 150 scientist-hours, respectively, to survey. But the effort required climbed rapidly for smaller-bodied, more cryptic, less well-known groups—1600 hours for the beetles, 2000 for the termites, and 6000 for the nematodes (Lawton *et al.*, 1998). Despite the fact that this work as a whole took about five scientist-years, inventories for most groups that were surveyed were still only partial, and most taxa remained unexamined (fungi, higher plants, spiders, soil mites, collembola, earthworms, lizards, frogs, and mammals, to name some of the most conspicuous gaps).

Given this background, it is hardly surprising that biologists do not have a complete inventory of all the species that occur even in a single, moderately sized area (a field, small wood, or lake)—a so-called ATBI (All Taxa Biodiversity Inventory) (Oliver and Beattie, 1996). A moments thought will also show that to use one or two groups (for the sake of the argument, say birds and butterflies) as indicators of the richness of other taxa in fact requires *several* such areas to be investigated to properly test the hypothesis that high bird diversity (or any other single group) reflects a high diversity of many other groups.

Although progress has been made in this area over the past decade, considerable work remains to be done. Even in otherwise well-studied situations, many groups remain to be examined. Hence, at the present time, and effectively by default, some groups are being used as indicators of biodiversity, even though we cannot show categorically that the richness of one or more groups of organisms truly reflects the overall, or even a major portion of the overall, biodiversity of an area. As a result there is little consensus about what a “good” indicator group, or groups, might be, because there are too few hard data, from a range of habitats and geographic regions round

the world, on which to draw firm conclusions. But as data slowly emerge, they are not encouraging for those who wish to use simple, single-taxon indicators of biodiversity.

Indicator Reliability

Where knowledge exists, it suggests that single or small numbers of taxa will usually be poor indicators of the biodiversity of other groups.

Tropical versus Temperate and Other Major Diversity Gradients

It would be wrong to think that there is no coincidence between patterns of diversity in different groups of organisms. Of course there is. In the broadest terms, it is axiomatic that most major terrestrial and freshwater groups are more species rich in the tropics than in temperate regions, at low elevations than at high ones, in forests than in deserts, and on large land masses than tiny islands. Whether you are a botanist, a bird-watcher, or a bug hunter, to find the most species it is generally advisable to head to hot and humid mainland tropics with lots of trees. It is easy to assume that there must therefore be reasonably good correlations between major diversity gradients for different groups. There can be, but even at this scale often there are not. Penguin diversity peaks in Antarctica, not the tropics, and there are many other examples of similar “reverse diversity gradients” that buck the average trend. On the eastern side of North America, the diversity of breeding warblers *increases* from south to north—suggesting that this conspicuous taxon, which is easy to identify (at least the breeding males!) and to survey, is probably highly unsuitable as an indicator of patterns of biodiversity in most other taxa (in which diversity typically *decreases* from south to north).

In the case of breeding North American warblers, we can spot the problem because we have enough information about the organisms involved. But the whole point about indicator taxa for biodiversity is that typically we will not be armed with, and indeed should not need, information about “other” groups; knowledge of the indicator taxon should suffice and be reliable. The evidence suggests otherwise.

Hot Spots

Major gradients in diversity aside, at similarly large scales an indicator group might be used to identify local geographic hot spots in the species richness of one or more other groups (peaks in the landscape of species richness) or to determine relative levels of richness in those other groups (hot spots versus all spots) (Gaston, 1996b; Reid, 1998). At the continental scale, the procedure has frequently been found to fail on both counts (Gaston, 1996a), with mismatches between the occurrence of peaks in the richness of different groups being commonplace.

Across the United States and southern Canada, hot spots (local areas with unusually high diversity) overlap partially between some pairs of taxa (trees, tiger beetles, amphibians, reptiles, birds, and mammals), but the pattern is not a general one. Numbers of species in different large grid cells for two groups are often significantly positively correlated, for example, birds and tiger beetles or mammals and swallowtail

butterflies. But these correlations are frequently weak, of rather limited predictive value, and in some cases explained by latitudinal gradients in diversity. In other words, although such correlations may sometimes enable a very general impression of the patterns in richness of one group to be obtained from the patterns in richness of another, their predictive powers are low.

These conclusions seem to hold at finer resolutions over more constrained areas. Thus, species-rich areas for different taxa in Britain (birds with butterflies, dragonflies, etc.) frequently do not coincide at a scale of 10×10 km squares (Pendergast *et al.*, 1993) (Figure 5). Hot spots in this study are not distributed randomly, overlapping more often than expected by chance, but still at a low level. Likewise, different taxa are species poor or species rich in different areas of the Transvaal region of South Africa. At even finer scales, within the Cameroon forest mentioned earlier, disturbance impacted on the diversity of eight taxa in very different ways. All declined drastically in completely cleared areas, but intermediate levels of forest disturbance had very different effects on the diversity of different groups. As a result, changes in the diversity of one taxon could not be used to predict changes in the diversity of any other (Lawton *et al.*, 1998). A summary of these and related studies showing similar results is provided by Gaston (1996a, 1996b) and by Pimm and Lawton (1998).

A Common Sense Explanation

This lack of, or relatively feeble correlation between, species rich-areas for different groups of organisms makes the search for simple, robust, single-taxon indicators of overall biodiversity look increasingly like a lost cause. With hindsight, perhaps this emerging result is obvious (Reid, 1998). Major geographic gradients in biodiversity aside, within particular geographic regions or at smaller habitat scales, the conditions favoring one group of species may be hostile to another. Mollusks like it cool and wet, butterflies like it warm and sunny, and high bird diversity is more likely in tall vegetation than short vegetation, irrespective of weather. Common sense natural history suggests that there is unlikely to be a single indicator taxon able to predict the diversity of all, or even a majority of others.

Rare Species and Endemic Species

Biologists and conservationists are often interested not only in patterns of species richness but also in the distribution of unusually rare species, or of endemic species. Do sites with unusual numbers of rare species frequently coincide across different taxa? Again, the answer seems to be no, or only weakly (Pimm and Lawton, 1998; Pendergast *et al.*, 1993), for the reasons just outlined.

Endemic species may be different (Bibby *et al.*, 1992). There is some evidence that areas rich in endemic birds (e.g., some tropical mountaintops or isolated islands) may also contain unusually large numbers of endemic species in other groups. However, rigorous data and analyses are few, and exceptions are easy to find. Lake Baikal has no endemic birds but supports an exceptionally rich, endemic invertebrate fauna and a unique, endemic freshwater seal.

Figure 5 Coincidence between hot spots for butterflies and up to seven other taxa in Britain. Hot spots are unusually species-rich sites (here defined as the top 5 percentile in Britain). All of the most species-rich localities in Britain for butterflies lie in southern England. Increasingly dark shading indicates that butterfly hot spots coincide with hot spots for an increasing number of other taxa. Note that many butterfly hot spots are not unusually rich in any other species (open circles) and that only one locality (in southeast England, just in from the coast) is a hot spot for all eight taxa in this particular survey. The other taxa are breeding birds, dragonflies, moths, mollusks, aquatic higher plants, and liverworts (simple plants). Reproduced from Prendergast JR, Quinn RM, Lawton JH, Eversham BC, and Gibbons DW (1993) Rare species, the coincidence of diversity hotspots and conservation strategies. *Nature* 365: 335–337, with additional data and figure kindly provided by John Prendergast.

Selecting Areas to Conserve Biodiversity: Conservation Planning and Reserve Selection Algorithms

Biodiversity Indicators and Conservation

The general lack of reliable indicator groups for biodiversity is undoubtedly unfortunate for scientists wishing to understand how life is distributed across the earth; the road to an atlas of biodiversity seems set to be a long one. In practice, it may actually prove somewhat less of a worry for one of the primary motivations in the search for indicators for biodiversity—namely, conservation planning. Networks of national parks and reserves are central planks in conservation, albeit alone they are insufficient to protect all species. Their establishment is one of the obligations placed on Parties to the Convention on Biological Diversity. A primary argument for using indicators of biodiversity is to determine the effectiveness of these protected area networks in capturing biodiversity, and the best ways in which they might be extended, in the face of stiff competition with alternative forms of land use.

Although hot spots of species richness coincide weakly for different taxa (see the previous section), if we turn the problem around and look at it from a different angle, an interesting picture emerges. Imagine that conservation priorities in Britain have been set by concentrating just on areas rich in birds (the bird hot spots). (Although the general view of many nations is that the British are mad about birds, the country's protected area network is not based solely on birds. We use the example simply to illustrate a point.) What we discover is that the hot spots for this one group tend to embrace a high proportion of the total species in other groups. Thus, the hot spots for breeding birds contain 87% of the breeding bird species in Britain, 100% of the butterflies, 92% of the dragonflies, 92% of the liverworts, and 94% of the aquatic plants. A reserve

network established around hot spots for one group does a rather good job of ensuring that most species in other groups find a place in the extended ark of protected sites.

Reserve Selection Algorithms

Although this message is encouraging, it turns out that designing conservation networks simply on the basis of levels of species richness is extremely inefficient, at least if the goal is to capture representative samples of all taxa. The same species may occur repeatedly in different richness hot spots for a group. Conservationists do not have unlimited resources, and this duplication wastes money on purchasing, or managing, unnecessary land. On the other hand, some species, particularly the rare ones of primary conservation interest, may not occur in any richness hot spots at all. What is required is to identify those areas that constitute the greatest complementary species richness; the complementary part of an area's biota consists of those species unrepresented in another biota with which it is being compared. To do this, mathematically minded conservation biologists have developed powerful reserve selection algorithms that help to select sites with maximum efficiency, according to some predetermined criteria (Pressey *et al.*, 1993). The criteria may be to maximize the number of species, rare species, or endemic species in a proposed reserve network, at minimum cost, on a minimum area, closest to existing reserves, or what have you.

Echoing the conclusions of the previous section, the question then arises as to whether the patterns of complementarity of one group of organisms are congruent with those of another. The question is a new one, with few studies available to answer it. Across 50 forests of Uganda, which boasts more species for its size than almost any other country

in Africa, and consistent with our earlier conclusions, there was little spatial congruence in the species richness of woody plants, large moths, butterflies, birds, and small mammals once differences in sampling effort were accounted for. However, sets of forests selected using complementarity determined for single taxa were generally similar to those for all other taxa and hence served to capture well the species richness in all these other groups (Howard *et al.*, 1998).

If these results generalize to other parts of the world, they send an encouraging message to conservation managers struggling to identify the best areas to set aside as reserves and parks. It says that a complementary and therefore efficiently selected chain of reserves based on a single indicator taxon (or perhaps two or three indicator taxa) may efficiently capture complementary sets of many other groups as well. Unfortunately, the Ugandan results are not supported by similar studies in the Transvaal, elsewhere in Africa (van Jaarsveld *et al.*, 1998). It may therefore be too soon to assume that we can find simple indicators for complementary reserve sets embracing many taxa as a means of conserving biodiversity.

Conclusions

The term “indicator species” has three distinct meanings. They are a species, or group of species, that reflect the biotic or abiotic state of an environment; reveal evidence for, or the impacts of, environmental change; or indicate the diversity of other species, taxa, or entire communities within an area. The uses of indicator species in the first two senses of the word are very similar, differing largely in the fact that to indicate change, organisms need to be sampled more than once in the same place and in the same way. Using organisms to indicate the state of, and changes in, the environment has numerous tried and tested applications, from detecting pollution to monitoring recovery of formerly degraded habitats, at many scales, from local to global. The use of indicator species to predict the diversity of other, unstudied taxa for scientific or conservation reasons is much more contentious and may prove to be impossible with any degree of rigor.

Glossary

Dominant species Species that owe their influence to their high abundance. Such organisms account for most of the biomass in a community, and thus are the primary components of community structure. Trees in forests, mussels in rocky intertidal habitats, grasses in grasslands, and kelps or corals in near-shore subtidal habitats are all dominant species.

Interaction webs (functional webs) Subset of species that through their interactions and responses to abiotic factors make up the dynamic core of food webs or communities. These webs include keystone species, dominants, and other strong interactors.

Key-industry species Prey of intermediate trophic status that support a large group of consumers.

Keystone species Consumers that have a large effect, and one that is disproportionately large relative to their abundance, on communities and ecosystems. Uniquely, the strong effects of keystone species on their interacting species exert extensive influence, often indirectly, on the structure and dynamics of communities and ecosystems. They are a

distinct subset of a more broadly defined set of “strong interactors” that also include species having strong effects on interacting populations but not necessarily on communities or ecosystems. Keystone species can include predators, parasites, pathogens, herbivores, pollinators, and mutualists of higher trophic status, but generally are not plants, sessile animals, or “resources.”

Strong interactors (foundation species) Species that have a large effect on the species (one or a few) with which they interact. Communities and ecosystems may have many strong interactors, and such species may occur at all trophic levels. “Strong interactors” is a more general term that can include keystone species, but not all strong interactors are keystone species. A similar idea is “foundation species,” defined as the group of critical species whose effects and interactions define much of the structure of a community.

Weak interactors Species that have little effect on other species, at least under average conditions. Under some circumstances, weak interactors may occupy important roles in ecological communities as a result of changes that lead to temporary increases in their abundance, size, or biomass.

Historical Perspective

Identification of *Pisaster ochraceus* as a Keystone Species

In 1966, Paine reported the results of a study of the role of predatory sea stars in structuring marine intertidal communities on a rocky shore on the outer coast of Washington State. In temperate regions, such communities typically display a striking spatial pattern called “zonation.” The hallmark of this pattern is that dominant space-occupying organisms are arranged in vertically stacked horizontal bands. For example, wave-exposed rocky temperate shores can have a band of barnacles on the upper shore, a band of mussels on the middle shore, and a band of macroalgae on the lower shore. On the Washington coast, the macroalga-dominated “low zone” also harbors various mobile and sessile invertebrates, including limpets, chitons,

sea urchins, whelks, anemones, and, significantly, the sea star *Pisaster ochraceus*. An intriguing feature of the zonation pattern was the sharp demarcation between the mussel bed and the low algal zone. Observing that the low-zone-occupying sea stars fed regularly on mussels, and the only abundant source of mussels was higher on the shore in the middle zone, Paine postulated that predation by sea stars determined the sharp lower limit to mussels. Specifically, he speculated that at high tide, sea stars moved up from their low-tide resting places in the low zone to remove prey from the lower edge of the mussel bed, then retreated back to the low zone where the prey were consumed.

Paine tested the hypothesis that sea star predation determined the lower limit of the mussels by periodically removing *Pisaster* from a section of a rocky outcropping and comparing this section to an area in which sea stars had been left at natural densities. Within 3 years, the mussel *Mytilus*

californianus had increased in abundance, causing a reduction in local species richness of macroorganisms from 15 to 8 species (Paine, 1966). Ultimately, after 10 years of excluding sea stars, a single-species monoculture of *M. californianus* dominated the shore (Figure 1). Ancillary studies suggested that this change depended on two important mechanisms. First, *Pisaster* preferentially fed on mussels. This sea star actually will feed on many invertebrate species, but given a choice, it selects mussels. Second, mussels were dominant competitors for space. Field observations, and later experiments, indicated that mussels could displace all other occupants of space, including macrophytes, sessile invertebrates, and mobile invertebrates, by crowding them out. In doing so, mussels also created habitat for a sharply different set of invertebrate cryptofauna that occupied the byssal “forest” (the fibers that mussels use to attach to the rock) beneath the mussels.

Paine later repeated this experiment on a nearby coastal island (Tatoosh Island) with essentially identical results, further demonstrating that under natural conditions *Pisaster* indirectly enhances the persistence of other space occupiers by preventing mussels from invading the low intertidal zone. The striking difference in species composition and physical appearance of the low zone community wrought by the sea star, a community member that was nowhere close to being “dominant” either numerically or in biomass, was the basis for Paine’s identification of *Pisaster* as a keystone predator.

Note that contrary to some uses of the concept, the original definition did not comment on keystone species as determinants of species diversity. Although the changes in species diversity that occurred in Paine’s (1966) field experiments revealed an important role of such species, Paine and other early workers on the topic (Estes *et al.*, 1978) evidently did not consider these changes to be fundamental to the concept of keystone species.

The formulation of the keystone species concept contributed to a gradual shift in ecological thought. Throughout the 1960s and 1970s, most ecologists believed that competition was the most important process structuring communities. By the late 1960s, advances in ecological theory and modeling, in conjunction with comparative and experimental field studies, demonstrated that processes other than competition could be important. Experiments such as those described above were among the first to show how predation can dramatically affect community structure. Following Paine’s pioneering work, ecologists began to identify keystones in other systems.

Are There Others? Keystone Predators Elsewhere

One of the first documented examples of a keystone predator in another system was the sea otter, *Enhydra lutris*. Estes *et al.* (1978) observed subtidal communities in the Aleutian Islands, Alaska, where sea otters were abundant and differed

Figure 1 Results of *Pisaster* removal experiments. Upper diagrams: “Reference” shows the natural interaction web in the low zone, and “Removal” shows the interaction “web” (i.e., *Mytilus*) 10 years after removal began. Arrows point to the species or group affected. Solid arrows show direct effects; dotted arrows show indirect effects. “Minus” by an arrow indicates that the effect was negative; “plus” by an arrow indicates that the effect was positive. Lower diagrams: Left and center show covers of *Mytilus*, other sessile invertebrates (barnacles, anemones), and algae in 1963 (beginning of experiment) and 1973 in the presence and absence of *Pisaster*. Right diagram shows difference between covers in 1973 and 1963 for each group of sessile organisms. “Direct” indicates that increase in mussel cover was due to direct predation by sea stars. “Indirect” indicates that decreases in sessile invertebrates and algae were an indirect consequence of sea star predation, through competitive elimination of sessile invertebrates and algae by mussels. Data from Paine, 1974, cited in Power ME, Tilman D, Estes JA, *et al.* (1996) Challenges in the quest for keystones. *Bioscience* 46: 609–620.

from those in nearby areas where sea otters had been locally extirpated by hunting. In waters surrounding islands with sea otters, kelp forests at shallow depths dominated nearshore subtidal communities, and within these kelp forests sea urchins, an important consumer of kelp, were relatively small and urchin biomass was low (Figure 2). On neighboring islands without sea otters, however, sea urchins were large, urchin biomass was high, and kelps were absent. On the basis of these data and the observation that sea otters preferentially feed on sea urchins, Estes and coworkers postulated that sea otters are a keystone species in this community. They argued that predation by sea otters reduced sea urchin grazing, thereby maintaining kelp forests and associated species. By documenting the “keystone predator” phenomenon in a different ecosystem, this research bolstered the view that such dynamics were potentially widespread.

Subsequent work supported this hypothesis and expanded our understanding of the conditions facilitating a keystone role for sea otters. In a large-scale study published in 1995, Estes and his colleague David Duggins determined the spatial generality of sea otter effects and tested the prediction that

Figure 2 Total cover of macroalgae and sea urchin density by depth at three locations on Amchitka Island – Kirilof Point, Bat Island, and Kirilof Rocks (all with sea otters) – and one at Shemya Island (without sea otters). ▲, vegetation cover; ●, sea urchin density. Reproduced from Estes JA, Smith NS, and Palmisano JF (1978) Sea otter predation and community organization in western Aleutian Islands, Alaska. *Ecology* 59: 822–833, with permission from ESA.

after sea otters colonize new areas, sea urchin-dominated subtidal communities would become kelp-dominated (Estes and Duggins, 1995). Surveys in the Aleutians and in southeast Alaska showed that the differences associated with sea otter presence or absence in the earlier studies were general in space – kelps were abundant in the presence of sea otters and scarce in the absence of sea otters. Further, considering all surveyed sites, sea urchin and kelp abundance were strongly inversely correlated (Figure 3). Finally, sea urchin abundance declined sharply at sites invaded by sea otters but did not change at sites where sea otter abundance remained constant. An interesting regional difference was that rates of increase in kelp abundance in the presence of invading sea otters were higher in southeast Alaska. Estes and Duggins suggested that higher rates of kelp increase resulted from differences in the recruitment of sea urchins, which was much greater in the Aleutians than in southeast Alaska (1995). Coupled with sea otter preference for larger, adult urchins, higher recruitment rates of

Figure 3 Density of kelp (individuals per 0.25 m²) vs. estimated sea urchin biomass (gram per 0.25 m²) for the Aleutian Islands and southeast Alaska. Points show averages for sites within locations. Sea urchin biomass was estimated from samples of population density, size–frequency distribution, and the functional relation between test diameter and wet mass. Reproduced from Estes JA and Duggins DO (1995) Sea otters and kelp forests in Alaska – Generality and variation in a community ecological paradigm. *Ecological Monographs* 65: 75–100, with permission from ESA.

Figure 4 Changes over time in (a) sea otter abundance at several islands, (b) sea urchin abundance, (c) grazing intensity, and (d) kelp density at Adak Island in the Aleutian archipelago. Error bars are 1 SE. Diagrams to the left and right of the data panels suggest the mechanisms leading to the changes. The left diagram shows kelp forest dynamics without orcas and the right diagram shows changes induced by the addition of orcas as the top predator. Thick arrows show strong effects, and thin arrows show weak effects. Reproduced from Estes JA, Tinker MT, Williams TM, and Doak DF (1998) Killer whale predation on sea otters linking oceanic and nearshore ecosystems. *Science* 282: 473–476, with permission from American Association for the Advancement of Science.

juvenile urchins presumably led to moderate rates of grazing on kelp sporelings and juveniles in the Aleutians, slowing rates of increase in kelp abundance relative to those in southeast Alaska.

A recent complication with troubling conservation implications suggests that killer whale (*Orcinus orca*) predation has begun to eliminate sea otters from their native habitats, with predictable consequences for abundances of sea urchins and

kelp (Figure 4). During the 1990s, sea otter abundance declined sharply at several Aleutian Islands. Once freed from sea otter predation, sea urchin populations increased, leading to severe declines in kelp and associated species. Estes and coworkers suggested that killer whales may have shifted their diet from large marine mammals to sea otters ultimately as a consequence of human activity. Overfishing and increased ocean temperatures (due to global climate change) are associated with declines in forage fish for sea lions and seals, and consequently these marine mammals have declined sharply in number. Historically, these large marine mammals have been the primary prey of killer whales; in their absence, some orcas have shifted their diet to otters. Because sea otters are small relative to pinnipeds, rates of predation loss have evidently been high, with substantial direct and indirect consequences for subtidal communities.

Generalization and Liberalization of the Definition: Other Types of Keystone Species

These earliest examples of keystone species were of consumers that modified the community through predation. However, some investigators suggested that species other than top predators could play keystone roles in communities. Subsequently, a variety of different types of organisms were termed “keystone” species, including herbivores, plants, pollinators, pathogens, habitat modifiers, and mutualists. The remainder of this article presents examples of such alternative keystones, summarizes a critique of these ideas, and offers proposals for further clarification of keystone and other functionally important species.

Herbivores

By consuming primary producers, keystone herbivores can have dramatic impacts on community structure. Among species identified as keystone herbivores are kangaroo rats and bison. In the Chihuahuan Desert, Brown (1998) (see summary) suggested that a guild of kangaroo rats played a keystone role. In plots where kangaroo rats were excluded, grass cover increased threefold. This was accompanied by a change in species composition; species shifted from those typical of desert shrubland to those characteristic of arid grasslands (Figure 5). The mechanisms responsible for this transition were seed predation and soil disturbance by kangaroo rats. Preferentially eating the seeds of competitively dominant grasses, kangaroo rats indirectly released subordinate plant species from competition. Furthermore, kangaroo rat burrowing favored disturbance-tolerant plant species. Hence, the presence or absence of kangaroo rats determined whether the community was desert shrubland or arid grassland.

Note that this example both extends the concept to herbivores and attributes the keystone effect to a multispecies group instead of a single species. Recently Brown (1998) suggested that the kangaroo rat effect was attributable primarily to two species, *Dipodomys merriami* and *Dipodomys spectabilis*. *D. spectabilis* went locally extinct in 1994, so if the system persists unchanged well beyond this extinction, *D. merriami* may be a keystone species. In this study, however, the original interpretation of these herbivores as a keystone “guild” may contribute

Figure 5 Densities of perennial and annual grasses in the presence and absence of kangaroo rats (*Dipodomys*). Data are mean percent cover (± 1 SE) of *Eragrostis lehmanniana* (ERIN), other tall perennial grasses (PERG), *Aristida adscensionis* (ARAD), other tall annual grasses (ANNG), and the short annual grasses *Bouteloua aristoides* (BOAR) and *Bouteloua barbata* (BOBA). Top: Data from transects inside enclosures from which kangaroo rats had been removed or allowed to remain. Asterisks above bars indicate significant differences between + kangaroo rat and – kangaroo rat enclosures. Bottom: Data from transects outside the respective enclosures. Asterisks between panels indicate significant differences between transects inside and outside plots where kangaroo rats were present or absent. Analyses employed ANOVA with plots as units of replication; *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$. Reproduced from Brown JH and Heske EJ (1990) Control of a desert–grassland transition by a keystone rodent guild. *Science* 250: 1705–1707, with permission from American Association for the Advancement of Science.

to confusion in terminology. This study is an excellent example of the strong effects of consumers on community structure, but as explained later, it was not designed to discern between keystone and “diffuse” (multispecies) predation.

Bison have also been identified as keystone herbivores (Knapp *et al.*, 1999). Studies at Konza Prairie have documented strong effects of bison on species composition, diversity, and several physical and chemical aspects of ecosystem function of grassland communities. These patterns occur across scales ranging from the plant level to patches to

landscapes, and are largely a consequence of bison preference for competitively dominant grasses and for persistent habitat features. As will be discussed later, Knapp and coworkers also evaluated the question of whether or not bison are truly keystone herbivores using the operational procedure recommended by Power *et al.* (1996).

Plants (Resources)

Terborgh (1986, cited in Power *et al.*, 1996) suggested that certain plants in Peruvian rain forests can provide keystone "resources." Most tree species in these tropical rain forests fruit in synchrony. However, when these species are out of season, palm nuts, fig trees, and nectar-bearing plants can provide a crucial resource to frugivores. Less than 1% of the plant biomass of tropical forests is made up of these species and yet virtually all frugivorous animals rely on them during the 3 months when other food sources are rare. Consequently, Terborgh argued that these plants maintained high animal diversity in these communities and therefore occupied a keystone role. Although Terborgh's work focused on Peru, he suggested that keystone plant resources may be widespread in tropical rain forests.

In another example, Willson and Halupka (1995) suggested that anadromous fishes swimming upstream to spawn, or their carcasses, were suggested to be keystone resources. They argued that a large number of vertebrate predators and scavengers, especially terrestrial species, rely on the energy input provided by anadromous fishes returning to their natal streams. Such energy sources can be strong interecosystem links and are suggested to have an influence on the diversity of terrestrial mammal assemblages.

The notion that such species or resources can be important to community dynamics is not disputed in this article, but for two reasons, describing these species as keystones is questioned. First, in most such cases, the evidence for keystone effects is weak and conjectural; the investigators have not demonstrated that removal of the resources would lead to wholesale community changes. Second, it is widely believed that the top-down effects (such as keystone predation, keystone herbivory) are qualitatively distinct from bottom-up effects (e.g., primary production and food supply). Therefore, the authors suggest that the examples in which plant-level processes are thought to determine consumer effects, and which thus suggest that the plant is the keystone species, serve to confuse rather than clarify the concept by combining under a single idea a heterogeneous collection of ecological processes. Although the evidence in favor of the role of bottom-up effects as important determinants of community dynamics is strong, these effects commonly lead to variation in top-down effects, often with single species (i.e., keystones) having large effects that are disproportionate to their abundance. It is therefore argued here that retaining the original distinction of keystone species as consumers is simpler and clearer, and hence better serves both understanding and insight into community dynamics and policy decisions regarding ecosystem management and conservation. Studying the role of bottom-up processes as determinants of community structure is an exceedingly important area of research, but the authors believe that the progress both in this area and in the role of keystone species will be enhanced if they are treated as distinct but dynamically linked concepts.

Mutualists (Pollinators, Seed Dispersers)

Flying foxes (*Pteropus* spp.) have been proposed to be keystone "mutualists" in tropical rain forests. Flying foxes are large tropical bats that are important pollinators and seed dispersers in Old World forests and on tropical islands. Especially on isolated islands where other vertebrate pollinators are scarce, these bats can be responsible for dispersing 80–100% of the seeds. Cox and coworkers (cited in Power *et al.*, 1996) argued that, through these pollination and dispersal "services," flying foxes may be responsible for maintaining high plant diversity in the forest communities in which they occur. Comparisons of the proportion of fruits and seeds dispersed by flying foxes on Guam, where flying foxes have been driven nearly to extinction, and on Samoa, with abundant flying foxes, were consistent with this idea (see Rainey *et al.*, 1995, cited in Power *et al.*, 1996). Fruits dispersed by flying foxes on Western Samoa were between 0% and 100%, whereas 0–1% of seeds were dispersed by flying foxes on Guam. Such data are only suggestive; however, further study is needed to demonstrate that the forest community structure reflects these differences in fruit and seed dispersal, and that flying foxes play a keystone role in determining community structure.

Habitat Modifiers

Organisms that influence the availability of resources for other species by modifying the physical environment have also been considered as keystone species. The term "ecosystem engineers" has been coined to identify such organisms (see Lawton and Jones, 1995, cited in Power *et al.*, 1996). Beavers, red-naped sapsuckers, kangaroo rats, and prairie dogs are all examples of species that, through their nonforaging or nontrophic activities, modify and/or create habitat for other species. By altering the hydrology of rivers, beaver dams can have profound effects on sediment retention, nutrient cycling, and the condition of the riparian zone (Naiman *et al.*, 1986). Sapsuckers create habitat for two species of swallows by drilling holes in aspens. In addition, their feeding holes in willows create sap flows, providing a resource for several species of birds, mammals, and insects (see Daily *et al.*, 1993, cited in Power *et al.*, 1996). The activities of kangaroo rats and prairie dogs cause soil disturbance, which affects community structure. These habitat modifiers were all thought to have impacts disproportionate to their abundance and were thus dubbed keystone species.

Critique and Reevaluation

Paine's original definition of keystone species referred to top predators that greatly modified the species composition and physical appearance of the ecosystem by preferentially feeding on the dominant competitors for space. Although not quantitative, the term was clear in concept and interpretation. As documented in the section Habitat Modifiers, however, the term was subsequently applied to a variety of organisms other than top predators and to actions that affected communities in ways other than feeding on competitive dominants. Application to groups of species (e.g., keystone guilds) rather than to a single species blurred the concept even further. These definitional liberalizations, combined with a lack of rigor in determining if candidate species meet the necessary criteria to be

termed “keystone,” eventually undermined the usefulness of a potentially powerful concept (Mills *et al.*, 1993). Here, these issues are evaluated and a scheme of classification and definition (slightly modified from that offered by Power *et al.*, 1996) is suggested, which further clarifies and advances the usefulness and application of the concept of keystone species.

Reevaluating the Keystone Species Concept

The seeming lack of a working definition of keystone species prompted Mills *et al.* (1993) to argue that careless usage had sufficiently degraded the value of the concept to justify its removal from usage. They further argued that because the term was poorly defined it was functionally useless and conservation strategies therefore should not be based on protecting keystone species. They advocated focusing on interaction strength rather than on a species’ keystone or nonkeystone status as a more useful management strategy.

In response to the criticism by Mills *et al.* (1993), a group of ecologists with expertise in the study of keystone species and strongly interacting species met to evaluate the keystone species concept. The publication that resulted from this meeting was a signal achievement, and much of the present article is patterned after this synthesis (Power *et al.*, 1996). The group agreed with Mills *et al.* (1993) that through misapplication and questionable redefinition, ecologists and conservation biologists had obscured the meaning of the term keystone species. Rather than abandoning the concept, however, the group proposed clarification and adherence to a set of more sharply defined concepts for community dynamics. They defined a keystone species as “one whose impact on its community or ecosystem is large, and disproportionately large relative to its abundance” (Power *et al.*, 1996). This definition retained the essence of Paine’s original usage, but expanded it more broadly to include species other than predators.

Power *et al.* (1996) stressed the importance of having a rigorous, quantitative method of assessing the community- or ecosystem-level effects of a species when determining if it is a keystone. To assess a species impact on a community, they proposed a community importance (CI) index, which in practical terms is quantified experimentally as

$$CI_i = [(t_N - t_D)/t_N](1/p_i)$$

where p_i is the proportional abundance of the species i before it was deleted, t_N (for “normal”) is a quantitative measure of a community or ecosystem trait under usual conditions (e.g., productivity, nutrient cycling, species richness, and relative abundances of species), and t_D (for “deleted”) is the trait in the absence of species i . Keystone species are those whose CI is large relative to that of other species (Figure 6). On the basis of these considerations, Power *et al.* suggested that if the total impact of a species is plotted against its proportional abundance, keystone species would cluster toward the upper left of the graph in Figure 7. Power *et al.* (1996) defined another group of species, “dominants,” as those that had large total impacts but in proportion to their abundance – these would lie to the upper right of the abundance–impact diagram.

Importantly, keystone species are not necessarily simply “strong” interactors, at least as the terms are defined here.

Figure 6 Possible frequency distributions of community importance (CI) values for all species in a community. Positive values occur when a community trait decreases after a species is deleted. For instance, in the absence of a mutualist, the target dominant species would also decrease. Negative values occur when a community trait increases after removal of a species. For instance, in the absence of a consumer, the target dominant species would increase. Community importance values may be normally distributed around zero (a), indicating that most species have small effects and keystones are rare. In some communities (b), CI values may have several modes, with keystone species indicated by values far from zero. Reproduced from Power ME, Tilman D, Estes JA, *et al.* (1996) Challenges in the quest for keystones. *Bioscience* 46: 609–620.

Keystone species not only have disproportionately large effects, but also have a community or ecosystem-wide impact through direct and indirect effects cascading through the system (Power *et al.*, 1996; see Figure 1). Strong interactors are species that have a large impact on the species with which they interact, but this large impact could affect only a single interacting species. Only when strong interactors have multi-species effects that alter the structure of the community, or the functioning of the ecosystem, are they also keystone species.

Related Concepts

The idea that not all species have equal significance in community dynamics is an old one, and many efforts have been made to assign names or terms to distinguish species or groups of species with important roles. Elton (1927) advanced the concept of “key-industry species” as single species of animals supporting a large number of consumers (e.g., copepods,

Figure 7 Total impact of a species (absolute value of community impact $\times$ proportional abundance of a species) vs. its proportional abundance, p_i . Species whose total impact is proportional to their abundance would fall along the diagonal line $X=Y$. Keystone species have effects that greatly exceed their proportional abundance, both on a per capita (or per biomass) basis and a per population basis, and would cluster toward the upper left region of the diagram. To illustrate, some organisms (e.g., rhinovirus, V_R , which causes colds in wildlife) may have effects that are greater than expected from their biomass, but because the impact on the community is relatively minor, they are not keystone species. Others (e.g., distemper virus, V_D , a killer of lions or wild dogs) may have collective effects on the community that are disproportionately large, and would be keystone species. Examples of keystone species are *Pisaster* (P), sea otters (O), predatory whelks (*Concholepas*, C), and freshwater bass (B). Dominants are high proportional biomass species whose large effects are not disproportional to their biomass, such as trees (T), giant kelp (K), prairie grasses (G), and reef-building corals (Cr). Positions of each species or group represent educated guesses. Reproduced from Power ME, Tilman D, Estes JA, *et al.* (1996) Challenges in the quest for keystones. *Bioscience* 46: 609–620.

herring, anchovies, and sea pens). “Foundation species” were defined as the “group of critical species which define much of the structure of a community” (Dayton, 1972). Related ideas include “interaction webs” and “functional webs,” which are defined as the subset of strongly interacting species that regulates community structure (Menge and Sutherland, 1987). A similar idea, the “extended keystone hypothesis,” states that ecosystems are controlled by a small set of key plants, animals, and abiotic processes. Note, however, that the latter phrase adds environmental stresses (“keystone processes”) such as fire, wave-induced damage, substratum movement, and other kinds of disturbances to the biological forces stressed by the other concepts. A contrasting view that biotic and abiotic forces are qualitatively distinct suggests the term “critical processes” to describe abiotic effects that can structure communities.

Recommended Terminology

Although the various generalizations of the keystone concept and the lumping of several related concepts into a broad keystone species definition were well intentioned, this study agrees with Mills *et al.* (1993) and Power *et al.* (1996) that such usage sharply reduces the utility of the keystone species concept. On the basis of current usage and the documented

need and desire for clarity in standardized terminology, the adoption of the following terminology is proposed. Species in communities can be defined as:

- **Keystone species:** Consumers having a disproportionately large effect on communities and ecosystems. By this definition, keystone species can include predators, parasites, pathogens, herbivores, pollinators, and mutualists of higher trophic status, but not plants, sessile animals, or “resources” (e.g., salmon carcasses, salt licks, and deep pools). To date, no convincing examples of communities with more than a single keystone species are known. Therefore, the suggested hypothesis is that most communities will have at most a single keystone species. At the ecosystem level, which might include several distinct communities, there may be several keystone species. Evaluation of these predictions awaits future research.
- **Strong interactors (critical species):** Species having a large effect on the species (one or more) with which they interact. Communities and ecosystems may have many strong interactors, and such species may occur at all trophic levels. Strong interactors would lie toward the upper side of the abundance–impact diagram (Figure 7), and therefore include both keystone species and dominants.
- **Weak interactors:** Species having little effect on other species, at least under average conditions. Under some circumstances, weak interactors may occupy important roles in ecological communities as a result of changes that lead to temporary increases in abundance, size, or biomass (Berlow, 1999). Weakly interacting species would all lie toward the lower portion of Figure 7.
- **Dominant species:** As noted above, dominant species are those strongly interacting species that owe their influence to their high abundance (Figure 7). Such organisms are the species that comprise a large proportion of the biomass in a community, and thus are the dominant components of community structure. Trees in forests, mussels in rocky intertidal habitats, grasses in grasslands, and kelps or corals in nearshore subtidal habitats are all dominants.
- **Key-industry species:** As defined earlier, key-industry species are prey that support a large group of consumers. Following Elton’s (1927) usage, key-industry species are therefore animals of intermediate trophic status.

Groups of species in communities or ecosystems can include:

- **Interaction webs:** Interaction webs (= functional webs) are the subset of species that through their interactions and responses to abiotic factors make up the dynamic core of food webs or communities. Interaction webs include keystone species, dominants, and other strong interactors.

Identification of Keystone Species

Lack of experimentation and other rigorous approaches to identify keystones continues to be a pervasive problem. In many cases, species are named keystones based on superficial evidence such as natural history observations. A lack of rigor in identification could result in mislabeling a species as a

keystone and inferring that it is the primary determinant of the structure of its community when in fact it is not. As noted by Mills *et al.* (1993), this can yield a serious loss of credibility with respect to policy and management decisions.

Despite limitations of spatial and temporal scales and other shortcomings, experimentation supplemented by comparison remains the most powerful tool available for revealing the dynamics of communities and ecosystems (Paine, 1994). In many cases, however, practical, legal, and ethical concerns preclude manipulations of suspected keystones (e.g., sea otters, killer whales, or prairie dogs). It is clear, therefore, that the identification of keystone species must necessarily use a variety of approaches. In addition to the comparative-experimental approach, alternative approaches include path analysis, sensitivity analysis, the study of natural or accidental invasions, the study of the consequences of overexploitation, and exhaustive and detailed comparison coupled with natural history and ideally small-scale ancillary experimentation (Power *et al.*, 1996). Inferences based solely on descriptive natural history knowledge (e.g., diet composition and frequencies, behavior, and abundance) are likely to be misleading. For example, under natural conditions a keystone predator may rarely consume the competitive dominant in a system (because it has sharply reduced the prey's availability), and thus be overlooked as a possible regulator of the dominant or the community. In the sea star system studied by Paine (1966), for example, barnacles, not mussels, were the most frequently consumed prey. Thus, although natural history knowledge is fundamental to the understanding of the dynamics of any ecological system, much additional evidence is necessary before the ecological role of a species can be determined.

Experimental Approaches

Keystone species are often identified by removal or exclusion experiments; that is, the presumed keystone is deleted from a portion of the habitat, and the effect of the removal on the community is compared to a separate, control portion of the habitat. One problem with this approach is that if a suspected keystone species is removed but there is no detectable response by the community, it is not possible to conclude that the community lacks a keystone species. In such a case, three alternative interpretations are possible. (1) Predation is weak overall, such that no predator deletion will produce an effect. (2) Predation is strong and there is a keystone species in the community, but it was not the species removed. (3) Predation is strong but diffuse, and multiple predators would need to be removed to produce an effect.

To tease apart these alternatives, an appropriate experimental protocol in testing for keystone predation (Menge *et al.*, 1994; Navarrete and Menge, 1996) should include:

Treatment	Explanation	Tests
1. + Predators	Intact community, all predators present	Control or reference ("natural" community state)
2. – Predators	Quantifies total predation effect, all predators removed or excluded	Strong vs. weak predation

3. – Single predator	Quantifies single species effects, deletion of each predator species singly, leaving the others present	Keystones vs. diffuse predation
----------------------	---	---------------------------------

For example, if consumer species are removed both collectively and singly, but predation is weak, the total effects of predation and the effects of each species with respect to their impact on community structure will be small (Figure 8(a)). With strong predation regimes, keystone predation would be indicated if total removals and removal of just one of the predator species were similarly large (Figure 8(d)). Finally, diffuse predation would be indicated if removal of each predator species singly led to significant but substantially smaller effects than removal of all predator species (Figure 8(g)).

This protocol also has important implications for understanding how communities or ecosystems might respond to loss of trophically high species (Allison *et al.*, 1996). In a system where predation is weak, of course, loss of species should have little effect (Figure 8(a–c)). With strong diffuse predation, where each consumer has an impact on community structure, species loss may lead to little change in the system as a result of compensation by the remaining consumers, at least until most consumers have been lost (Figures 8 and 9). In both cases, the community response to species deletion is relatively predictable (Allison *et al.*, 1996). With strong keystone predation, however, the consequence of species loss is relatively uncertain (Figures 8 and 9). By definition, compensation by the weakly interacting predators, while possible, is not likely to fully account for the loss of the keystone species, and if the identity of this species is not known *a priori*, the system response is highly uncertain (see Figure 9).

This protocol has rarely been used, but two examples illustrate its efficacy. Menge *et al.* (1986) evaluated the separate and combined impacts of most combinations of four groups of consumers in rocky intertidal communities in Panama. The extremely high diversity of this tropical community imposed an immediate compromise in their design: Simultaneous single-species removals were essentially impossible because >40 consumer species were relatively abundant. The compromise was to remove major consumer groups (i.e., omnivorous crabs, omnivorous fishes, predatory whelks, and grazing molluscs), each consisting of several common species. Their partial factorial design (difficulties in separating crab and fish effects meant only 12 of a possible 16 treatments could be conducted) included treatments assessing the effects of removing consumers in single groups and in total. After 3 years, none of the single-group removals produced an effect similar in magnitude to the exclusion of all the consumers (Figure 10). Removal of two and three groups produced changes in prey that were intermediate between single-group and total exclusion treatments. Thus, total predation pressure in this system was high but the effect of individual groups was small. The lack of prey responses from single-group removals compared to the increasingly strong responses from removals of two, three, and all four groups suggests three things: That, up to a point, groups can compensate for reductions in other groups; that there was no keystone species in this system; and that predation was diffuse.

Figure 8 Total effects (solid bars) of a consumer group and effects of single species (open bars) under three regimes of predation effect, with possible responses to sequential loss of single species. Panels (a), (d), and (g) represent the intact assemblage; (b), (e), and (h) represent the changes in the absence of species 1; and (c), (f), and (i) represent the changes if both species 1 and 3 are removed or lost. Panels (a), (b), and (c) show change with weak predation; (d), (e), and (f) show changes with strong keystone predation; and (g), (h), and (i) show changes with strong diffuse predation. In the absence of the keystone species, the remaining species have a small impact on the community (f). In contrast, with diffuse predation, the remaining species compensate strongly for the loss of a consumer so that predation remains strong. Reproduced from Allison GW, Menge BA, Lubchenco J, and Navarrete SA (1996) Predictability and uncertainty in community regulation: consequences of reduced consumer diversity in coastal rocky ecosystems. In: Mooney HA, Cushman JH, Medina E, Sala O, and Schulze E-D (eds.) *Functional Roles of Biodiversity: A Global Perspective*, pp. 371–392. Chichester, UK: John Wiley & Sons.

In another study, Navarrete and Menge (1996) tested the relative intensities of predation on the small mussel *Mytilus trossulus* by the original keystone species, the sea star *P. ochraceus*, and coexisting predatory whelks, *Nucella emarginata* and *N. canaliculata*, on the Oregon coast. In a fully factorial design they quantified rates of predation on mussels in all combinations of presence or absence of each. Their results indicated that, as predicted, *Pisaster* had the strongest effect, by far, on mussel survival (Figure 11). Although whelk effects were almost undetectable in the presence of sea stars, they were relatively strong in the absence of the sea stars. Thus, *Pisaster* was the keystone predator in these experiments. Whelks were weak interactors in the presence of sea stars, but, via compensatory increases in density, had moderately strong effects on mussel survival when sea stars were absent.

Nonexperimental Approaches

To be convincing, comparative evidence needs to be extensive in space and time and to incorporate a wide range of approaches. One of the most convincing examples of the

determination of keystone species on the basis of description and comparison is the sea otter example described earlier. Another convincing example is that of beavers as keystone species (Naiman *et al.*, 1986). By building dams across streams and through feeding activities, beavers can have profound effects on the structure and dynamics of aquatic ecosystems. Beavers alter hydrology, channel geomorphology, productivity, and biogeochemical cycling at a magnitude far exceeding their proportional biomass in these systems.

Bison are another good example of keystone species designation based on largely nonexperimental evidence (Knapp *et al.*, 1999). Extensive and detailed studies at the levels of individual leaves, individual plants, plant populations, and landscapes showed that selective grazing at the level of species and patch greatly altered patterns of community structure. Bison preferred grasses in burned areas and revisited these sites repeatedly establishing a distinct high-diversity mosaic pattern of vegetation. Their grazing on grasses and avoidance of forbs resulted in high levels of species diversity, high spatial heterogeneity, and high nitrogen availability in tallgrass prairie. Moreover, bison grazing interacted with fire, another

Figure 9 Relationship between the ability of a group of consumers to maintain a system at some persistent state ("ecological role fulfilled") and the regime of predation. (a) Diffuse predation: In moving from left to right on the abscissa, the remaining species compensate for the loss of other species, maintaining similar structural patterns in the community or ecosystem until most are lost. (b) Keystone predation: As species are lost, dramatic changes in structure can occur with each removal, but unless the identity of the keystone species is known, prediction of when such changes occur is uncertain. Reproduced from Allison GW, Menge BA, Lubchenco J, and Navarrete SA (1996) Predictability and uncertainty in community regulation: consequences of reduced consumer diversity in coastal rocky ecosystems. In: Mooney HA, Cushman JH, Medina E, Sala O, and Schulze E-D (eds.) *Functional Roles of Biodiversity: A Global Perspective*, pp. 371–392. Chichester, UK: John Wiley & Sons.

natural element of tallgrass prairies, in ways that enhanced the patchiness, diversity, and nitrogen availability, and generated intermediate levels of net primary productivity. As mentioned earlier, estimates of the CI of bison indicate that these large grazers clearly have a large effect, one disproportional to their biomass, on plant community structure and ecosystem functioning.

Space does not permit further detailed citation, but other convincing examples of keystone species are available from marine, freshwater, and terrestrial habitats, including those cited in Table 1 in Power *et al.* (1996). Many more examples than these are available in the literature that are based on

Figure 10 Effect of consumers, collectively and by each of four single groups (fishes, crabs, whelks, and molluscan grazers), on total prey abundance in the rocky intertidal region at Taboguilla Island, Panama. Prey included sessile invertebrates (mostly barnacles and bivalves), colonial invertebrates (hydrozoans), and algae. The estimate of the effect of consumers was based on the percent cover of prey in the absence and presence of all consumers (total) and each group separately. Single-group effects were estimated by determining the difference between treatments that differed in whether or not the particular group was included in the treatment. For example, fish effects were estimated by treatments $+F + C + W + G$ vs. $-F + C + W + G$, $+F + C - W + G$ vs. $-F + C - W + G$, etc. Error bars are 1 SE. Reproduced from Menge BA, Lubchenco J, Ashkenas LR, and Ramsey F (1986) Experimental separation of effects of consumers on sessile prey in the low zone of a rocky shore in the Bay of Panama – direct and indirect consequences of food web complexity. *Journal of Experimental Marine Biology and Ecology* 100: 225–269.

limited evidence and thus remain conjectural. It seems clear, however, that the phenomenon of keystone species is real and widespread, and that a variety of approaches are available to document their existence and importance. What remains unclear from the foregoing is (1) whether or not there are keystone traits that allow *a priori* identification of keystone species, and (2) whether or not there are predictable conditions under which keystone species will evolve and persist. These issues are considered next.

Identification of Keystone Species *a priori*?

Field experimentation is not always feasible. Moreover, even where and when feasible, such studies are often time-consuming and expensive. It seems obvious that it is impossible to study each and every system on the Earth to determine the nature of interactions among species and how these influence community dynamics. For these reasons, an ultimate goal in ecology is to gain the ability to predict the roles of species and the processes underlying the dynamics of communities and ecosystems. Ideally, predictions would be based on observation and measurement of organismal,

population, and community traits and patterns. Evaluation of the reliability of such predictive traits would depend on cycles of study that identified important traits in particular systems and tested their predictive capacity in novel systems.

Figure 11 Results of a mussel transplant experiment. Data are the mean proportions of mussels (± 1 SE) surviving in each of four treatments at wave-exposed and wave-protected sites at two study sites, Boiler Bay (BB) and Strawberry Hill (SH). Treatments were all combinations of presence and absence of whelks (*Nucella* spp.) and sea stars (*Pisaster*). $\circ$, $-$ *Pisaster* $-$ *Nucella*; $\blacktriangle$, $-$ *Pisaster* $+$ *Nucella*; $\blacksquare$, $+$ *Pisaster* $-$ *Nucella*; $\blacktriangledown$, $+$ *Pisaster* $+$ *Nucella*. The experiment was begun 3 July 1993 and completed 30 August 1993. Reproduced from Navarrete SA and Menge BA (1996) Keystone predation and interaction strength: Interactive effects of predators on their main prey. *Ecological Monographs* 66: 409–429.

Traits originally suggested to characterize keystone species were differential impacts on prey species, high consumption rates relative to prey production, and a focus of the keystone's impact on dominant competitors in the system. A survey of well-studied keystone predator examples in marine and freshwater habitats, however, suggested that these, and several other postulated "keystone-identifying" traits, were not predictably associated with keystone species (Menge *et al.*, 1994, see Table 1). In all, 17 studies of strong predation were considered. Eleven were dominated by keystone predation and six were dominated by diffuse predation. As indicated in Table 1, differential predation and dominance of the community by a single prey species in the absence of the predator were characteristic of both keystone and diffuse predation systems, and thus do not serve as a distinguishing trait of keystone predation. Although data were limited, prey production rate was the only trait that consistently distinguished keystone (high prey production) and diffuse (low prey production) predation systems. No other potential trait was consistently associated with either type of system. Clearly further research is needed, but based on present knowledge, *a priori* identification of keystone species using traits alone does not seem possible.

Context Dependency

The role of a species as keystone can be context dependent (Menge *et al.*, 1994; Power *et al.*, 1996); that is, a species that serves a keystone role under some set of biotic and/or abiotic conditions may not serve under other conditions. For example, at exposed headlands along the Oregon coast, the sea star *Pisaster ochraceus* was found to occupy a role similar to that documented for this species in comparable habitats on the Washington coast (Menge *et al.*, 1994; Paine, 1966). On more wave-sheltered rocky shores, however, *Pisaster*'s role was weak to absent, despite the presence of populations of this sea star

Table 1 Summary of survey of potential keystone species traits in consumer-dominated aquatic communities

Trait	Number of interaction webs					
	Keystone predation			Diffuse predation		
	Yes	No	?	Yes	No	?
1. Differential predation	7	0	4	3	0	3
2. Predation focused on competitive dominant	9	0	2	4	0	2
3. High predator/prey size ratio	10	1	0	6	4	0
4. High functional/numerical response	8	2	1	6	4	0
5. Indeterminate growth of predator(s)	8	3	0	6	4	0
6. High predator mobility relative to prey	10	1	0	6	4	0
7. Spatial refuge for prey	6	4	1	3	2	1
8. Size refuge for prey	1	8	2	2	3	1
9. Space is limiting resource for prey	7	4	0	5	1	0
10. Low community diversity	3	5	3	2	2	2
11. Differential rates of prey recovery	6	1	4	4	0	2
12. High rate of prey production	5	0	6	0	2	4

Question mark means the conclusion is uncertain or unknown. For traits 3–6 the numbers under diffuse predation total >6 because several of the systems had several strongly interacting predators, each of which had a yes or no or ? conclusion.

Source: Reproduced from Table 10 in Menge BA, Berlow EL, Blanchette CA, Navarrete SA, and Yamada SB (1994) The keystone species concept – Variation in interaction strength in a rocky intertidal habitat. *Ecological Monographs* 64: 249–286.

Figure 12 Seawater temperature and sea star–mussel interaction strength (IS) during consecutive 14-day periods (abscissa). Data are means (± 1 SE) of values recorded at three sites. (a) High-tide water temperatures (the mean from 2 h before to 2 h after each high tide). Temperatures above the abscissa are the overall means for the 27 high tides of each period. (b) Mean per capita IS of sea stars on transplanted mussels during each 14-day period. (c) Mean per population IS of sea stars during each period. Both per capita and per population IS were lower during upwelling than during the other four periods. Reproduced from Sanford E (1999) Regulation of keystone predation by small changes in ocean temperature. *Science* 283: 2095–2097, with permission from AAAS.

at all locations studied (Menge *et al.*, 1994). The basis for this change was that environmental conditions changed with diminished wave impact. At one sheltered site, prey production rates (a combination of recruitment rates and prey growth) were so low that the sea star population consisted of a few scattered individuals. This and other studies suggest that sea star abundance is highest where food concentrations are high. At the other sheltered site, periodic and unpredictable burial by sand, not sea star predation, eliminated the competitively dominant mussels (*M. californianus*) from the lower shore (Menge *et al.*, 1994). Keystone predation in this system, then, depended on the spatial and environmental context in which the community occurred.

Keystone effects may also be altered by temporal environmental changes. Studies on the Oregon coast showed that *Pisaster* foraging activity is strongly suppressed during periods of cold water temperatures such as those occurring during periodic upwelling (Sanford, 1999; Figure 12). Laboratory and field studies in northern California demonstrated that sea star activity and behavior were sensitive to aerial temperature exposure as well, with chronic exposure to warm air temperatures at low tide leading to reduced feeding and growth rates and acute exposure causing increased feeding rates but no effect on growth rates (Pincebourde *et al.*, 2008). Further, the sea star also had the ability to respond to exposure to stress by taking a greater volume of water into its body, evidently to provide a buffer against the possibility of subsequent exposure to hot, desiccating conditions (Pincebourde *et al.*, 2009).

Although further study is needed to determine the broader significance of this result, sea and air temperature variation in time or space could also modify the community role of this species. In particular, alteration of upwelling patterns by global climate change could lead to community- and ecosystem-level modifications or shifts in community pattern over a broad geographic region. Thus, investigations conducted over a wide range of environmental conditions indicated that whether or not a species can fill a keystone role is dependent on physical and biological conditions (i.e., context).

In a second example of context-dependent keystone predation, juvenile steelhead were demonstrated to control summer food web structure in California rivers in years experiencing winter flooding. Steelhead were the top predator in a four-level food chain, and when present they controlled invertebrate predators, freeing herbivorous insects from consumer control and allowing them to control the abundance of algae (Power, 1990; cited in Power *et al.*, 1996). When steelhead were excluded, invertebrate predators increased and controlled herbivorous insects, resulting in a high biomass of algae. Winter floods swept these communities away, leading to annual cycles of community redevelopment, with shifts in algal biomass reflecting the development of successive trophic levels through the summer into autumn.

In years without winter flooding, predation-vulnerable herbivorous midge larvae (*Pseudochironomis*) were replaced by predator-invulnerable herbivores (e.g., aquatic moth larvae *Petrophila*, caddisflies *Tinodes* and *Glossosoma*) (Power, 1992, 1995; cited in Power *et al.*, 1996). The invulnerable herbivores sharply suppressed algal abundance and, due to their effective defenses against predators, effectively shortened the food chain from four to two levels. Thus, fishes (juvenile steelhead) were keystone predators in the context of years with winter flooding and were not in the context of years without winter flooding.

A variety of similar examples are available from all major habitats (see Table 2 in Power *et al.*, 1996), suggesting that context dependency is common and perhaps near-universal in ecological communities. Such variation may be a useful tool in investigating the conditions under which keystone species will evolve and persist. Understanding the conditions under which a species plays a keystone role is critical if ecologists are to build a predictive framework to evaluate the effects of global changes in biodiversity.

Interaction Strength

As noted earlier, keystone species are distinguished by both the strength of their interactions with other species and the large indirect consequences of these effects that occur through the structure of the food web. Since determining whether or not a species is a keystone depends on the rigorous application of methods that can quantify these effects, it is important to consider the concept of interaction strength. The patterning and dynamics of species interaction strengths (SIS) and the effects on ecosystem structure and dynamics has been a hot topic for both empirical and theoretical ecologists. Indeed, the variability and context dependency of the strength of species interactions is a great challenge for predictions of

ecosystem dynamics in response to perturbations (Agrawal *et al.*, 2007).

There are many measures of SIS. Both Berlow *et al.* (2004) and Wootton and Emmerson (2005) give comprehensive overviews of these various measures, how they relate to one another, and what their respective strengths and weaknesses are. The various kinds of SIS measures can be categorized into two main groups that measure effects at two different “levels” of a food web (Berlow *et al.*, 2004). The first are measures of SIS that refer to the property of an individual link. Theoretical models, such as the Lotka–Volterra models of interspecific competition, include a coefficient, α_{ij} , which “measures how strong the interactions are” of one species j on another species i (MacArthur, 1972). Maximum consumption rates and more complicated predator functional responses to prey density in predator–prey models are additional examples of interaction strength as a property of an individual link (Berlow *et al.*, 2004). These link-level measures of SIS are independent of the network context that the species are embedded in.

MacArthur (1972) also suggested a second meaning of interaction strength: Interactions can be considered strong if their “removal would produce a dramatic effect.” In this case, interaction strength refers to a system-level response of one species on the dynamics of another or on the functioning of the whole ecosystem. In the latter case, by our earlier definition, the strong interactor is a keystone species. Metrics that fall into this category of SIS include the number of secondary extinctions, or changes in one species’ abundance resulting from the removal or perturbation of another (Berlow *et al.*, 2004). Most empirical perturbation experiments fall into this category, since species manipulations impact the total direct and indirect effects of one species on another. Paine (1992), for example, quantified interaction strengths of herbivores (sea urchins, limpets, and chitons) grazing on kelp sporelings in field enclosure/exclosure experiments. Specific impacts of individual herbivore species were determined by comparing the densities of kelp sporelings that occurred in the complete absence of all herbivores (a measure of total herbivore pressure) to those occurring in the presence of single herbivore species (a measure of a single species’ total effect). Thus, even though Paine’s study was focused on specific food web links, the outcome of any perturbation experiment will include all direct and indirect, trophic and nontrophic effects between the species. The interaction remains embedded in its network context and is considered a systems-level response, not a property of an individual link that is independent of the network. This is an important distinction, especially for estimates of weak interactions, which exhibits the greatest variability, likely because when the direct effect is weak, there is a greater influence of indirect interactions (Berlow, 1999).

Despite these issues, system-level measures of SIS remain the most useful tool for distinguishing between systems with keystone versus “diffuse” predation regimes and identifying keystone species for conservation. System-level measures of SIS automatically take into account nontrophic (i.e., non-foraging) interactions, such as ecosystem engineering, interference competition, stress amelioration, and behavioral modifications, which can have important consequences for

community structure and dynamics, as it is described above for beavers, sapsuckers, kangaroo rats, and prairie dogs. Unlike trophic interactions, nontrophic interactions have no clear theoretical framework and are unwieldy to include in models of link-level SIS embedded in large ecological networks. However, attempts are being made toward resolving this problem (Arditi *et al.*, 2005; Goudard and Loreau, 2008; Kefi *et al.*, 2012).

These two distinct approaches to measure SIS have created a gap that has long divided theoretical and empirical investigations of food web dynamics (Laska and Wootton, 1998). However, recent work is bridging this gap and leading to exciting new insights. Novak and Wootton (2010) show how reformulating two of the most commonly used system-level measures of SIS, Paine’s index and the Dynamic index, can relieve some of their assumptions, such as linear predator functional responses and populations closed to immigration. In addition, Novak and Wootton (2008) describe an observation-based empirical method for estimating interaction strengths of an individual link that is directly comparable to most theoretical estimates. The method estimates species-specific attack rates of consumers expected to exhibit a saturated feeding rate at high-prey density (i.e., a type II functional response). Novak tested this observational approach in the rocky intertidal on the strength of predation of a whelk, *Haustrum scobina*, on its mussel prey, *Xenostrobus pulex* (2010). The observational method produced estimates in high concordance with experimental estimates derived from a best-fit predator–prey model of year-long mussel population dynamics under replicated manipulations of the whelk (Novak, 2010).

Several recent investigations have predicted SIS based on constraints imposed by bioenergetics as described by the Metabolic Theory of Ecology (MTE, Brown *et al.*, 2004). The basis of the MTE is that body size and temperature are critical determinants of metabolic rate, which is the fundamental process affecting higher-level processes in organisms, such as consumption rates. Emmerson and Raffaelli (2004) explored the relationship between predator/prey body size ratios and the strength of species interactions in the Ythan Estuary food web. They found that the patterning of predator and prey body sizes affects the arrangement of interaction strengths and increases the probability of stability in a model food web. Berlow *et al.* (2009) used allometric scaling rules to describe the relationships between body size, metabolism, and food consumption. Putting allometrically scaled parameters into a dynamic food web model led to a realistic method of predicting SIS simply from species body sizes and abundances. Recent laboratory studies have begun to test these theoretical allometries and parameterize food web models by directly measuring the effect of body size and temperature on estimates of link-level SIS (e.g., Rall *et al.*, 2010). Results to date are consistent with the MTE and show great potential for the use of allometric–trophic network models, based on body mass and trophic information, for identifying keystone species and predicting the effects of climate change on food web structure and dynamics.

Despite the issues of reconciling the many theoretical and empirical meanings and measures of SIS, common patterns have emerged over the past two decades. Field evidence for a

strong effect of body size on SIS comes from a study that quantified the relative influences of several biotic and abiotic factors on SIS in rocky intertidal ecosystems using species manipulation experiments (Wood *et al.*, 2010). Another common pattern is that communities repeatedly exhibit only a few strong and many weak interactions (e.g., Bascompte *et al.*, 2005; Paine, 1992; Wood *et al.*, 2010). Furthermore, it appears that the distribution of SIS is nonrandom within a food web. Bascompte *et al.* (2005) analyzed the distribution of SIS in the large pelagic marine food web of the Caribbean Sea. SIS were structured nonrandomly, with the likelihood of two strong interactions connected through two consecutive levels of the food web occurring less frequently than expected by chance. When strong interactors did occur on consecutive levels of the food web, they were accompanied by the stabilizing effect of strong omnivory more often than expected by chance. Using a food web model the authors showed that this patterning of SIS reduced the likelihood of trophic cascades after removing top species from the web, as would occur with fishing.

The discoveries of these patterns have considerably advanced the understanding of how SIS structures communities. Nevertheless, the causes and consequences of variability in species interactions are just beginning to be understood. One interesting example of how context-dependent variability in SIS results in a stable community structure is a study of the strength of predation on juvenile barnacles in small to large patches of cleared rock, which otherwise had an invariant pattern of sparse barnacle cover (Navarrete and Berlow, 2006). Small patches were maintained by predation from whelks and by adult barnacles filtering potential larval settlers, but predation in larger patches was low since the adult barnacle could not filter very far away from themselves and the whelks do not venture far away from the protection of the large barnacles. Thus, the variability in predation strength led to a stable pattern of barnacle abundance.

Keystone species will be those with large *per capita* SIS. Identifying such interactors in this way has shed light on the traits, both individual and community, that generate species with high *per capita* effects. As implied by the alternative meanings for interaction strength offered by MacArthur (1972), however, species impacts will also vary with density. Regardless of how large its *per capita* effect, a single individual will never have the same impact as that of many individuals (Berlow *et al.*, 1999; Navarrete and Menge, 1996). Thus, full understanding of interaction web dynamics, and whether a species is a keystone, a strong interactor, a weak interactor, or a dominant, will depend on knowledge of both *per capita* interaction strength and per population interaction strength. Also note that only a keystone species will have high values of both *per capita* and per population indices of interaction strength, at least at the community or ecosystem level.

Conservation Implications

Biologists are increasingly being asked to inform management decisions concerning the preservation of biological diversity

and ecosystem “integrity.” Because keystone species can be critical to maintain the species diversity and ecosystem functioning, some have argued that focusing conservation on them should be a priority. A current topic of debate is how best to design reserves, both marine and terrestrial, that will protect species diversity.

Many species have been presumed to be keystones based on observation and conjecture. In many cases no experimental removals were done to determine the actual effect of the species presumed to be a keystone on the rest of the community. As outlined earlier, identification of keystones should involve manipulations to quantify the effect of the suspected keystone on the community. However, from a management standpoint this is not always feasible. It sometimes takes years for field manipulations to yield results, whereas conservation decisions often need to be made in a much shorter period of time. Also, as noted earlier, in addition to potential time constraints, manipulations of some suspected keystones may not be practically feasible or ethical. Removing killer whales, sea otters, lions, polar bears, or other large, charismatic, and often endangered species is not a realistic option. The logistical difficulties in designing controlled enclosure or removal experiments for animals of large size and/or with large ranges are daunting.

Despite the difficulties, and accepting the view that conservation should focus on ecosystems rather than species, the keystone species concept offers several important insights that are relevant to management (Power *et al.*, 1996):

- Seemingly scarce and unimportant species may have unexpectedly large, dramatic effects on communities and ecosystems.
- Conserving species may depend strongly on other species in the community with which the target species has little seeming association, whether as prey, competitor, mutualist, or predator.
- Loss of a species, particularly one high in the food chain, may have surprising and extensive consequences for the remainder of the community or ecosystem.

All these points suggest that great caution is necessary before decisions are made that may result in the loss of a native species or the introduction of exotic species. In this study the authors recognize and agree with the need to make management and policy recommendations on the basis of present knowledge. The authors also suggest that although much has been learned and the pace of new knowledge is increasing, the current state of knowledge is still insufficient to allow making such recommendations with a high level of confidence. In particular, additional study is needed on those putative keystones for which evidence is scant, and continued study is needed on ways to detect keystone species and systems with keystone species. Other urgent issues are to determine the commonness of keystone species and keystone-dominated systems, the patterns of interaction strengths in representative communities, and the environmental and organismal conditions and traits that foster keystone species.

The authors conclude that the concept of keystone species is a powerful one, having broad importance and application to ecological theory, ecosystem dynamics, and conservation.

Many problems remain to be answered, but important advances on these issues are continuously being made.

Glossary

Chemostat Apparatus for growing microorganisms in a continually replenished medium.

Community A multispecific aggregation of organisms in a particular location that may interact with each other.

Competition More than one species utilizing one or more common resources.

Ecological niche The set of requirements that must be met if a particular species is to survive. It is sometimes used to mean the place in which those requirements are met.

Ecosystem A region with more or less clear boundaries, which contains a particular set of species and may be characterized by some set of meteorological, climatological, and geochemical properties.

Invasive or alien species Species that have recently colonized some geographic regions different from the one in which they were initially described.

Isocline A line along which some property remains constant.

Multidimensional niche A tempero-spatial region defined by meeting a set of different requirements for viability of a particular kind of organism.

Niche dimensions Ranges of values of environmental measurements in an ecological niche. A range of temperatures, salinities, or oxygen concentrations may be niche dimensions for a population of fish.

Packing The placement of objects in a container.

Reification The assignment of empirical reality to the referenda of a word or theory, regardless of the existence of any such referenda.

Species diversity The number of different species in some area of interest. Global species diversity refers to all species. Local species diversity refers to some geographic region such as Hawaii or New York City.

Species packing The study of how species on the same trophic level coexist in a limited region or container.

Introduction: The Biological Packing Metaphor

Different locations vary conspicuously in the number of species that are present. Some, like coral reefs and tropical rain forests, are famous for their high species diversity, while others, like some Alaskan forests, are notably monotonous in the number of kinds of trees that are present. Differences in diversity have attracted many researchers, although as yet there is no one all-encompassing theory of species diversity. In fact, the overall term “species diversity” seems more useful at the level of scientific policy and public relations than it is at the level of scientific discourse.

There are many theories and models of species diversity, which differ in their foci and assumptions. The theory of species packing is concerned with one aspect of diversity, specifically the coexistence of populations of different species located in a particular space. It carries elements of the concept of “species richness” in that the greater the species richness of a region, the more species have presumably been “packed” into it. It also carries implications for “realized species niches” because it might be inferred that the more species are packed into a region, the narrower the realized niches.

Like so many of the terms of theoretical ecology, “species packing” often is used in a metaphorical sense, which can be misleading. It is best to begin by analyzing the concept in a literal and elementary way.

The word “packing” has at least two meanings, which can cause confusion. It may mean placing objects inside a wrapper or container without altering them, or it may mean squeezing

them in to a fixed-size container. Contrast the packing of glass tumblers with that of pillows. Tumblers are packed into a container but if they press hard against each other they shatter. Pillows can be squeezed into a container and fluffed up again when they are taken out.

The possibility of either type of species packing presupposes some sort of container into which things are packed. Is the inferred container equivalent to an environment? Does an environment have fixed geometric dimensions like a wooden box? A pond, a log, a rotting fruit—all can, in fact, be thought of as containers. However, environments can be defined in ways that may have more meaning to investigators than to inhabitants. Are the boundaries of a study area like La Selva, a political unit like Costa Rica, or a geographic area like Central America in some sense meaningful packing containers?

We will introduce the mathematical theory of species packing, examine how the theory has been exemplified in laboratory and field experiments, and, finally, consider the implications of species packing for field observations.

Two Species In One Container

Theory

The problem of species packing was crystallized in the apparently simple question: “Why are there so many kinds of animals?” Thereafter there has been a continual stream of

often controversial, difficult, and sometimes acrimonious papers on this subject.

Lotka-Volterra Equations

Species packing theories are concerned with species in an implicitly assumed *container*. The boundaries of the container are usually considered to be permeable to the flow of resources and energy but, unless specified, impervious to the passage of organisms. These are important assumptions.

The formal theory of species packing originated from the equation systems of Lotka, Volterra, and D'Ancona. Lotka considered that in the entire biosphere all individual organisms have similar resource requirements, and no resource is in infinite supply. Therefore, at some level there must ultimately exist a limit to the abundance of organisms and an inverse relation between number of species and number of individuals per species. Further analysis is required before this assertion becomes interesting.

Volterra and D'Ancona considered several species competing with each other for resources in a space through which resources flowed at a constant rate. Competition between species A and B can be considered in terms of pairs of isoclines on a two-dimensional phase space with axes N_A and N_B :

$$\frac{dN_A}{dt} = 0 = K_A - N_A - \alpha N_B$$

$$\frac{dN_B}{dt} = 0 = K_B - N_B - \beta N_A$$

in which the subscripts refer to the two species. The K values refer to the number of organisms present at what was called "population equilibrium" or "population saturation."

It was assumed that any single species population would remain numerically constant after K had been achieved, if the flow of resources and the physical conditions did not change. These simple equations are the starting point for many species packing theories.

The K and N values were initially considered as counts of organisms, but as the theory developed the K values were taken to designate some resource divided up among the organisms. It often helps to think of species abundance as being directly translatable to rate of consumption of a temporally renewable resource.

It was usually assumed that any individual organism will negatively affect the well-being of all the others in the designated space, as measured by their birth and death rates.

Organisms can affect each other by reducing the availability of resources. They can also alter the chemical or physical properties of the local environment. These alterations are referred to as "conditioning" or "crowding." Yeast cells secrete alcohol, which affects other yeast and bacteria. Beetles and mice change the odor of the environment. Mussels and barnacles physically crowd each other.

In elementary packing theory, a constant, α , represents the relative amount of the resources of species A consumed by each individual of species B and, conversely, β represents the crowding of the individuals of species B by one individual of species A. In the multispecies case, α_{ij} is taken as the effect of species j on members of species i .

The Ecological Niche

The possible outcomes for two species were often represented graphically in elementary texts by using a phase diagram with abundance or concentration of each of the two species as axes. The persistence of both species populations is only possible if the two isoclines cross.

For species N_A , the isocline connects the point ($N_A = K_A$, $N_B = 0$) to the point ($N_A = 0$, $N_B = K_B/\alpha$). At each point on this isocline, individuals of the relevant species are crowded enough that births and deaths are equal. The crowding is exercised by either con-specifics, the members of the other species, or some mixture of the two.

If two species are inoculated into a space in which each species can survive if alone, there are basically three possible outcomes:

- If an individual of one species impacts the con-specifics more than hetero-specifics, both species may persist. The two isocline cross at a "knot."
- Another possibility is that individuals of both species are more sensitive to the presence of the other species than to the presence of con-specifics. In this case, the outcome depended on the initial concentrations of the two species. The isoclines cross at a "saddle."
- The final case is one in which one species has a stronger effect on the other, but the second species does not have a very strong effect on the first. The isoclines do not cross.

These three cases are related to simple definitions of the ecological niche. In the first case, the container is considered to contain regions from two ecological niches. In the second case, the container is in the intersection between two niches, and in the third case the container is within the niche of the victorious species.

Laboratory Experiments

While the elementary theory is primarily of pedagogical rather than practical value, it did inspire several laboratory population studies in which populations of two species were actually placed in a container, provided with renewable resources, and permitted to interact.

The early investigations on macroscopic organisms required long periods of observation and repeated tedious counting. Some later laboratory population experiments were done. Current studies of laboratory population dynamics mainly use microorganisms and are primarily of genetic and evolutionary significance. Even in these studies there are significant ecological differences between results derived from liquid culture in test tubes, in chemostats, and those from colonies on semisolid gels.

Without attempting to review all laboratory studies it is possible to summarize insights that have proved relevant in designing field studies and that have suggested theoretical analyses or may be expected to do so in the future.

- Laboratory studies have demonstrated that a single container can be divided in ways that can be more interesting than simply differences in quantitative utilization of resources.

For example, when populations of a moth and of a beetle were placed in a container with intact wheat grains or with flour, the moths were eliminated. Both species survived in cracked wheat. Broken bits of glass capillary tubing added to flour also permitted two species persistence. The moth larvae were being eaten by the beetles unless they were sheltered inside the grains or in the glass tubes. This illustrated that spatial complexity can modify the relation between competing populations. In the absence of physical refuges, the relationship between the moth and the beetle becomes a predator-prey interaction combined with some competition for food. Examples in which the interaction between several species can vary between competition and predation are not uncommon.

No populations, except for those of some microorganisms, grow according to the Verhulst Pearl logistic equation of sigmoid growth. This is interesting because there still are those that will defend the use of this counter-to-fact equation in development of theory.

- As populations become more crowded there are changes in birth and death rates. These changes are always accompanied by other physiological, anatomical, and behavioral changes.

There is abundant evidence of psychological and physiological change caused by individual social history in mammals. While the effects of past history may be most dramatic in mammals, they have been found in essentially all animals and plants. Crowded trees show different shapes than those grown in uncrowded situations.

- The levels of population density that can be reached during population growth experiments are very much in excess of what the organisms would tolerate in nature, as indicated by the ubiquitous tendency of animals to escape from these containers in any way possible.

In one study it was possible to compare responses of house mice in closed and open spaces. When the confined mice became sufficiently numerous to empty their food trays they immediately developed reproductive and behavioral pathologies. Unconfined mice remained in a local area around their food trays until they could empty them after each feeding. They then immediately dispersed.

Flour beetles when crowded move to the surface of their medium and show a strong tendency to fly. This cannot be demonstrated in population vials but becomes apparent if the flour containing a crowded population of beetles is removed from the vials or the vials are unstopped (personal observation). Dispersal when crowded is also found in other grain pests.

In *Daphnia*, winter eggs (ephippia) are produced at an early stage of food stress. This permits descendants of the population to survive despite whatever occurs in the experimental container. Any pond or lake that contains *Daphnia* or other Cladocerans will contain abundant ephippia in its sediments. These may hatch after a long dormant period, introducing genetically distinct animals from an animal seed bank for many years, even if the emergent animals of a particular genotype cannot survive in most years.

Even *Hydra*, which have no locomotory organs, respond to crowding and food shortage by floating free of their substrate, which removes them from a locally crowded situation.

- Laboratory populations can sometimes be used to make some inferences about what may be occurring in nature, but the inferences are not necessarily direct.

Early students of *Daphnia* assumed that *Daphnia* condition the water in which they lived. It was later demonstrated that the sizes of *Daphnia* populations in the laboratory, over a crowding range 10 times that ever observed in nature, were linearly dependent on food supply. If conditioning was of importance, this linearity would be impossible and there would have been a curvilinear relation similar to that found in the relation between nutrient flow and population size in chemostat cultures of microorganisms.

This does not imply that *Daphnia* populations in nature are regulated by their food supply. It does imply that they are not regulated in any significant way by causing chemical deterioration of their environment, because over a range of crowding that greatly exceeds any that has been found in nature, no chemical effect has been found.

Clearly, laboratory experiments and theoretical models cannot adequately imitate nature. However, an experiment can be designed to consider a wider range of conditions than those that occur in nature. In that sense, nature becomes a subset of the experimental world.

In some cases there is a clear logical transition between theory, laboratory experiment, and field experimentation. Gause mathematically considered predation on a two-species competition system. He concluded that the coexistence of two species could, in principle, be stabilized by predation.

In laboratory populations, the coexistence of brown and green species of *hydra* was facilitated by either removal of some of the animals or by maintaining them in low illumination, demonstrating that coexistence could be stabilized by either a biological or a physical change in the container.

In a field experiment, Paine found that heavy predation of starfish on mussels prevented the mussels from eliminating their competitors. In this case, theory proposed a possibility, laboratory experiments demonstrated its reality, and the field experiment demonstrated its importance in nature. But even in this case there were dangers of misinterpretation. The theory and the laboratory and field experiments demonstrated that under some circumstances a predator might enhance the number of surviving species on the next lower trophic level.

Any loss of organisms imposed on a multispecies system relieves, to some extent, competitive pressure on the survivors, so that weaker competitors may survive. There is, however, an abundance of cases of predators locally eliminating prey species, as is now occurring due to feral cats in Australia and Hawaii.

Expanding the Theory of Packing

Many formal theories of species packing begin by complicating this two-species situation. Among the obvious complications are those in which the isoclines are permitted to be

curved lines, which may be interpreted as social interactions of various sorts. Also, changing the sign of the interactions could crudely mimic predation or symbiosis. Loss of organisms across the “container” boundary could be thought of as mimicking predation.

Expansion of the Theory to Multiple Species

The more general question is: How many species can be introduced into a space? Multiple species packing theory is mathematically more difficult because a multispecies theory cannot be conveniently represented as isoclines on a two-dimensional phase space. If a third species were to be added, the phase space would have to be three-dimensional and isoplanes would be needed instead of isoclines. For coexistence of three competing species, the three isoplanes would have to intersect somewhere in the region below the intersection of any two of the species isoclines.

In the case of multiple species packing, there can be a region in the multidimensional phase space in which resources are divided in such a way that all species can share, but only if each species is relatively strongly selflimiting and relatively mild in its effects on the other species present. The multiple species theory requires clarification of the notion of *ecological niche*. The ecological niche of a species is often considered as the full set of measurements of environmental properties that are relevant to the survival and persistence of that population. Hutchinson and his students developed this into an image of a multidimensional hyperspace.

If two hyperspaces do not contain common dimensions, then the occurrences of the species concerned are independent of each other. As more and more dimensions are identical, or very similar, the stronger are the competitive interactions between the two species. Competition is one partial explanation for replacement of similar species along gradients in such physical features as temperature and salinity.

How Similar can Coexisting Species be?

MacArthur and Levins asked: What might be expected if a third species invades a space in which two species are already resident? They simplified the situation by considering that all species concerned interact through competition on a single niche dimension, or at least a linear representation of a multidimensional niche. They also assumed simple distribution of resources along that dimension. If, for example, the niche dimension is some particular prey, one of the species might eat large specimens while the other eats only small ones.

They considered that the niche of any species would have a shape on any single niche dimension. If the niche can be represented by a straight line, the probability of an individual finding a bit of resource at some point on the line can be represented as an ordinate, generating a two-dimensional shape. If the shapes for several species overlap, then the intensity of competition is measurable in terms of the probability of the several species striving for the same resource—the product of the individual species-specific probabilities.

They could then consider species packing along a niche dimension. Given their assumptions, packing can be closer on any one dimension as the number of niche dimensions increases. If species are arranged in a one-dimensional array along a line, the closest stable packing is admissible when the niche spaces are rectangular and all K values are equal. These conclusions were strongly dependent on their assumptions.

More general conclusions were that closer packing is possible if niche dimensionality is high, niche breadth is small, and the environment is predictable and has high productivity. Centers of adjacent niches are in a multiplicative series of numerical value approximately 1.1.

If the single linear dimension of competition is considered more realistically, so that there is a multiplicity of niche dimensions, MacArthur and Levins concluded that interspecific competition could be less important. In fact, it is sometimes considered that multispecies packing involves as many niche dimensions as there are species. Tilman considers that this is only valid if the organisms are not fixed spatially (i.e., they are free to move about in the container).

Various authors, by slightly modifying the mathematical assumptions, could reach a variety of conclusions about the packing of niches. For example, it was possible to plausibly argue that niches could sometimes be packed infinitely closely.

MacArthur and Levins suggested, as a matter of convenience, that the shapes of niches projected onto a single niche dimension might be thought of as approximating normal distributions. Other shapes are, of course, imaginable.

Species packing became a rich field for construction of theories, which were not necessarily connected to specific biological observations and more. These theories each make slightly modified assumptions or focus on special cases of previous theories. For example, Roughgarden and Feldman considered the significance of shape differences as if the shapes could be empirically demonstrated. Distributions with “thick” tails permitted more species to coexist than those with thinner tails.

There were also studies of multispecies biological situations under natural or artificial circumstances, which used the term “species packing.” In these the connection with species packing theory was sometimes explicit but very often the general conclusions of theory were presented in the context of field data without explicit theoretical derivation. This appears to be due to the fact that explicit formal theory production becomes very difficult once more realistic elements of natural complexity are involved. This is typical of mathematical models, at least prior to the recent development of powerful computing machinery.

Sometimes the models were sufficiently complex, combining ecological and evolutionary predictions, that self-contradictory assertions were made within the same theoretical argument and were not noticed for years. For example, one study published in 1983 assumed absence of any genetic heterogeneity and then proceeded to discuss the genetic effects of selection, as noted by Taper and Case.

Niche Separation and Anatomical Difference

The exact ratio of minimum possible distinction between adjacent species can be derived from special, simplified, and

somewhat arbitrary assumptions. Depending on assumptions, it can be asserted that an infinite number of species can coexist, that an infinite number of species could coexist were it not for statistical variance in the parameters, that coexistence is contingent on number of dimensions in the hyperspace, or that species must differ anatomically by a specific ratio in order to coexist.

Hutchinson suggested the possibility that one might find in nature that niche hyper-volumes of the most closely similar, often congeneric, coexistent species would actually differ from each other by a factor whose value might be approximately 1.3. This seemed reasonable based on the common observation that genera are often represented in particular locations by large, small, and medium-sized species. Attention was focused on this by Lack for Darwin's finches, but its occurrence can be easily confirmed by examining intertidal snails of the American northeast coast or the eastern shores of the Mediterranean Sea (personal observation).

"Assembly rules" for competing species on islands were developed in part on the basis of size. These results were criticized on statistical grounds. Were the species distributions really departures from random?

One major step was missing in attempting to demonstrate that a theoretical niche overlap in a simplified mathematical model predicted a morphological ratio between anatomical parts. While Hutchinson expected that trophic structures like jaws might show the appropriate tightly packed ratio, the theoretical connection between niche shape or size and body shape or size seems absent except in very special cases.

It was never really clear why there should be a relation between the overlap of niche hyperspaces and any obvious anatomical differences. There is no rigorous and general way of theoretically deciding which of the infinite possible number of anatomical measurements that might be made is appropriate in any given case. By choosing the measurements correctly or by manipulating the data, almost any ratio might be achieved. Simberloff provided a firm critique of measuring the niche separation by anatomical differences. There is a clear connection between body size and the utilization of pre-existing nest holes by snakes, owls, chipmunks, weasels, and others, but any pair of nest hole utilizing species is almost certain to differ in many niche dimensions.

Species Diversity and Species Packing

Does species packing set limits to species diversity in nature? This would require that natural aggregations of organisms are organized into communities and their component guilds, which would act as "containers." Are natural aggregations of organisms in nature strongly mutually interdependent so that "packing in" more species or removing species already present should have discernible effects on those already present? Do cohesive communities of organisms or ecosystems actually exist in nature? Early ecosystem theorists believed in a "holistic" or emergent concept of ecosystems and communities. If these were real, they would constitute containers in which packing theory might be applicable.

There is an enormous literature related to how many species occur in particular locations. Recently there has been a

weakening of the basic notion of a natural community as a "container" in any serious sense. There is massive concern about the dangers of invasive species, but recent studies have returned emphasis to individual species and almost discarded the idea of integrated communities. There is a general condemnation of invasive species but they are particularly interesting from the standpoint of species packing. If invasions do not occur, it may be due to lack of opportunity. Large mammals cannot float across an ocean on logs or hide away in ballast tanks. However, if a species can invade a region, then in some sense the region was not packed full, or perhaps successful invasions necessarily result displacements of resident species.

The apparent invader purple loosestrife is sometimes found in dense stands that keep out other species, but other studies find that purple loosestrife had no apparent effect on native plant species and may have benefited native insect diversity.

Ruiz estimated that more than 90% of alien species in estuaries have made no discernible impact on the species diversity or species abundance distribution of the estuary. Levine and D'Antonio report that a "consistent positive relation between exotic species abundance and resident species diversity ... [suggesting] that invaders and resident species are more similar than often believed." Apparently some invasive species fit into niches that were in some sense empty.

To what degree is competition, and therefore species packing theory, a serious factor in nature and how could one tell? Attempts to answer this question sometimes hinged on naturalists' insights, sometimes on various statistical analyses, and sometimes on detailed natural history and experiments conducted in more or less natural circumstances. Each of these has its strengths, advocates, and opponents.

In what sense do communities depend for their continuity on particular species? American chestnut trees constituted almost a third of the large trees of the southeastern American forests in the early 19th century. While small specimens still exist, the chestnut trees were essentially wiped out by the Chestnut blight. The forest did not disappear. As noted by Hairston *et al.*, the southeastern forest is as dense with trees as it has ever been. The general appearance of the forests have not changed, but the oaks, which have to a large degree replaced the chestnuts, produce volatile organic compounds that are of biogeochemical significance (M. Lerdau, personal communication, 2000).

Davis, studying the northward expansion of forests after glacial retreat, noted that each individual species seemed to migrate at its own rate—there was no movement of the forest as a community marching together. Whittaker noted that distribution of trees on various environmental gradients was as individual trees, not as communities.

Conclusions

Theory, experiments, and natural history all suggest that communities are not tightly organized, so that species packing may not be strongly relevant in nature. In short, the popular image of an ecological community as an airplane in which each part has a vital role for the integrity of the whole is

dubious. There may be groups of species, in which each one is closely connected to a few others but only loosely connected to other groups.

The term “community” was once extremely useful and is still of pedagogic value if carefully used. As reified objects for research, the concept of communities is now threatening to become what Simberloff and Dayan have referred to as a “panchreston,” an idea as likely to generate confusion as enlightenment.

The prospect of a general species packing theory has melted away. Despite the unreality of the models, they did direct attention to what seemed to be a real phenomenon and encouraged experimentalists and field biologists to ask important questions.

Differences in species richness can be partially explained by a multiplicity of factors that do not necessarily relate to each other so as to permit formation of a single coherent theory. Each of the multiplicity of theories of diversity focuses on one or a few of the empirical factors that are known to enhance or diminish the possibility of species coexistence.

Many of these can be seen in laboratory experiments, which have the advantage of clarity but may be of questionable applicability. For example, local geometry complexity influences species diversity in nature as well as in the laboratory.

Certainly in some cases the term “species packing” is used in the sense of species being squeezed into a space. In several cases individuals of particular species in species-rich regions are believed to have a narrower range of activities than individuals of the same species in species-poor situations. Diet or nest sites may be more restricted. In these cases the individual organisms can be imagined to have been constricted by some packing process, like individual pillows in a crate but even this has two possible meanings depending on whether we are concerned with the population level or with individuals.

In comparing different locales, the range of variation among organisms within a unispecific natural population may be reduced when more other species are present. In the case of comparisons of different islands or lakes, this might be tentatively attributed to species packing.

Returning to the initial analogy of packing actual objects, an island is clearly a container. But if packing means filling the ecological space, either by pillows or tumblers, we would not expect islands or speciose lakes to easily admit invasive species. In lakes there may be enormous species richness of fishes, as in the ancient African lake cichlids, but I don't know of any comparisons showing that species-rich lakes show less within species, among individual variation, than species-poor lakes. Is the attempt to crowd multispecific collections of fish together in the same lake equivalent to packing glass tumblers rather than pillows? There is a general impression that species rich systems seem at least as likely to be invaded by exotic species as species-poor systems, violating our sense of what packing might mean.

If the container walls are not apparent but among individuals variation is reduced in one or more populations of a species, is this a sign of species packing? Does the mere fact that among individuals variation is reduced when more species are present imply that there must exist a container wall which may not be obvious?

The overall conclusion is that the theory of species packing does not conveniently predict very much about natural systems but that the images of packing that it generates do informally suggest interesting phenomena to look for.

Glossary

Coevolution Cycles of adaptation and counteradaptation that occur between interacting lineages.

Coevolutionary arms race The continuing bouts of coevolving defenses and counterdefenses that occur between hosts and parasites.

Conspecific brood parasites Brood parasites that lay their eggs in the nests of other individuals of the same species.

Egg rejection Host responses to parasitism that include ejection of parasitic eggs, abandonment of parasitized nests (usually with renesting), or a new cup built over a parasitized clutch.

Evolutionary equilibrium hypothesis The hypothesis that frequencies of acceptance of brood parasitism reflect an

equilibrium between costs and benefits of host defenses against parasitism.

Evolutionary lag hypothesis The hypothesis that hosts lack defenses against brood parasites because the defenses have not yet had time to evolve.

Generalist brood parasites Species that parasitize many (up to more than 200) host species.

Gentes (singular gens) Lineages of cuckoos in which individual females specialize on a single host and lay mimetic eggs.

Interspecific brood parasites Brood parasites that lay their eggs in the nests of other species.

Specialist brood parasites Species that parasitize only one or a few host species.

Natural History

Brood parasites lay their eggs in the nests of other individuals, which then raise the parasitic young at the expense of part or all of their own brood. Brood parasitism was noted by Aristotle and even earlier (approximately 2000 BC) in India. Brood parasitism is best known in birds, approximately 1% of which are obligate interspecific brood parasites that only lay their eggs in the nests of other species. Interspecific brood parasitism, however, has also been documented in insects and fish. Conspecific brood parasitism (CBP), in which individuals facultatively lay eggs in nests of conspecific individuals, is more widespread.

Brood parasites have generated intense interest in the public and scientific communities. Brood parasites tend to be vilified in the media because of a human tendency to moralize about such things as killing baby birds (which parasitic birds often do) and because at least some may pose a conservation threat to some of their hosts. Among scientists, brood parasites have generated intense debate about the coevolutionary processes that may be responsible for the seemingly maladaptive acceptance of parasitic eggs by hosts.

Adaptations of Obligate Avian Brood Parasites

Brood parasites search for host nests, synchronize their laying with that of the host, and often remove a host egg from nests they parasitize. Brood parasitic eggs often have unusually thick eggshells, are usually small relative to the size of the parasite (but large relative to the size of the host), often mimic the coloration of the hosts' eggs, and have rapidly developing embryos. All these traits increase fitness of the parasite by reducing competition with the host nestmates and making

parasitic eggs more difficult to detect and remove. Egg mimicry is most pronounced in specialist brood parasites. In the well-studied common cuckoo, the species as a whole is a generalist, but each individual female is a specialist member of a "gens." Any one region has only one to several coexisting gentes, but different arrays of gentes occur in different regions.

Brood parasitic nestlings also have a variety of mechanisms that enhance their ability to compete with host nestlings. Cuckoo nestlings have concave backs that they use to push out host eggs and nestlings, whereas several other brood parasites have specialized bill hooks that they use to kill nestmates. Some brood parasites apparently increase the amount of food hosts bring to them by mimicking the juvenile plumages or the complex mouth markings (the "gapes") of host nestlings or by having large mouths and intense begging behavior.

Because brood parasites do not have to engage in costly breeding activities such as incubation and nestling feeding, they often have more time and energy to devote to egg production. Some generalist brood parasites lay 40 or more eggs in a season; estimates for one tropical brood parasite suggest that more than 100 eggs per year are typical. Other brood parasites, however, may be only slightly more fecund than their hosts.

A Survey of Avian Brood Parasites

There are approximately 102 species of obligate avian brood parasites in five unrelated families (Table 1).

Cuculidae

The cuckoos are a diverse family that contains both parasitic and nonparasitic species. The Cuculidae has traditionally been

Table 1 Major groups of avian brood parasites

<i>Taxon (family/subfamily)</i>	<i>Number of species</i>
Old World cuckoos (Cuculidae) ^a	56
New World cuckoos (Neomorphinae)	3
Honeyguides (Africa and Asia) (Indicatoridae)	17
Viduline finches (Africa) (Ploceidae)	19
Cuckoo-finch (Africa) (Ploceidae)	1
Cowbirds (New World) (Icteridae)	5
Black-headed duck (South America) (Anatidae)	1

^aRecent work indicates that at least one genus in this subfamily belongs in another cuckoo subfamily (see text).

recognized as an Old World subfamily, all of whose approximately 56 species are obligate brood parasites. Most species are host specialists that are relatively uncommon and only a few have been well studied (the common cuckoo and the great spotted cuckoo). Another traditionally recognized subfamily, the Neomorphinae or New World ground cuckoos, has 11 species, three of which are relatively rare obligate parasites. The latter tend to parasitize hosts that build domed nests and are poorly known overall. Nestlings of one species, *Tapera naevia*, have pincer-like bills that they use to kill host nestlings, a case of convergence on honeyguides (Indicatorinae). Recently published DNA sequence data indicate that at least one genus (*Clamator*) within the Cuculidae is more closely related to the Phaenicophaeinae, a subfamily of New World cuckoos. None of the currently recognized members of the Phaenicophaeinae are obligate parasites but some parasitize conspecifics and occasionally other species. These new DNA data place obligate parasitism within three groups of cuckoos, two of which have both parasitic and nonparasitic species, and indicate that parasitism evolved separately up to three times in cuckoos or that some parasitic cuckoo lineages reverted to parental behavior.

Indicatoridae

The honeyguides, a family named for the habit of one species that guides people and the African honey badger or ratel to beehives, has 17 obligately parasitic species. The species of *Indicator* and three related genera parasitize cavity nesters, whereas three species of *Protodiscus* parasitize open-cup nesters. Most species are poorly known and the eggs of many species have never been described. Some honeyguides have raptorial hooks on their bills, which they use to kill host nestlings. Recent studies suggest there are two host-specific lineages of greater honeyguides, those that utilize burrow nesting hosts (bee-eaters and a kingfisher species) and those that use cavity-nesting hosts (woodhoopoes and another kingfisher species). These lineages have eggs that match host eggs based on size and shape rather than color because hosts nests in dark cavities in which color is not readily detectable.

Viduline Finches

The approximately 19 species of obligate brood parasitic viduines occur in Africa and provide some of the best examples of nestling mimicry, particularly of the intricate gape patterns of their hosts. However, the exact function of this

mimicry is unclear because when the color of the parasitic nestling gapes is experimentally altered it does not decrease likelihood of them fledging from host nests. Compared with other brood parasites, viduines exert relatively low costs on their hosts, which can usually raise mixed broods. Most *Vidua* species specialize on single species of grassfinches (Estrildidae), to which they may be related. Unlike most brood parasites, which are insectivorous, hosts of viduines are granivorous. Some species of viduines incorporate the songs of their hosts into their own songs, which are then used by females to choose males that have been raised by the same species.

Cuckoo-Finch (*Anomalospiza imberbis*)

This African species is closely related to viduline finches and parasitizes approximately 15 species of the Cisticolidae in grasslands. Similar to the common cuckoo there are apparently host-specific gentes that have evolved to circumvent host egg recognition. Recently reported DNA evidence suggests that parasitism evolved once in a single lineage that then gave rise to both *Anomalospiza* and the viduines.

Icteridae

The five species of New World brood parasitic cowbirds include the most generalized of all brood parasites, the brown-headed and shiny cowbirds, both of which parasitize more than 200 host species. Another species, the tropical giant cowbird, parasitizes almost exclusively colonial American blackbirds. Of the two remaining species, the bronzed cowbird is a host generalist (>100 host species), whereas the screaming cowbird is one of the most specialized of all brood parasites. It mainly parasitizes a single species of blackbird, which was formerly thought to be a species of cowbird. Unlike most brood parasites, cowbirds are often more abundant than many of their hosts and can pose a significant threat to populations of rare, localized host species. Most cowbirds benefit greatly from changes in the landscape caused by humans, which has enabled several species to expand their geographic ranges and increase their population sizes. As a result, they are coming into contact with new hosts that have not had recent contacts with brood parasitism. Some of these new hosts suffer extremely high levels of parasitism. Cowbirds appear to be extremely fecund; the shiny cowbird may lay more than 100 eggs a year. The invasion of North America by this cowbird may pose an additional threat to species that are not currently being parasitized by the brown-headed cowbird. The brown-headed cowbird may be the most intensively studied North American bird.

Black-Headed Duck (*Heteronetta atricapilla*)

This species is the only obligately parasitic species with precocial young that feed themselves when they hatch. For this reason, this brood parasite has little effect on the nesting success of its hosts, which only have to incubate an extra egg or two. *Heteronetta* has been recorded parasitizing 14 different hosts species, such as gulls and ibises, as well as other ducks.

CBP

Recent studies have shown widespread CBP, especially in waterfowl, gallinaceous birds, and in a small number of

songbirds (generally species with rare nest sites or that breed colonially).

Other Brood Parasite Systems

Fish

An African catfish is the only fish species known to be an obligate brood parasite. It parasitizes mouth-breeding cichlids and apparently consumes all of its host's young while in the mouth of its foster parent. CBP and occasional parasitism of other species occur in many nest-building fish. Some host defenses such as increased nest guarding may have developed in response to this parasitism but egg recognition has not been reported.

Insects

A range of insects practice brood parasitism, especially members of the order Hymenoptera (bees, wasps, and ants). Some of these species are obligate brood parasites, such as certain ants that kill the queens of nonparasitic species and use the workforce of the entire colony to rear their own young. Other species are facultative parasites that victimize conspecifics or raise their own young. To our perception, some of these parasitic insects look remarkably different from their hosts so their acceptance by hosts seems inexplicable. However, olfaction is critical to these insects and it is likely that parasitic species have evolved chemical cues that mimic those of their hosts. Because both humans and birds perceive the world largely via vision and audition, and have relatively poor olfactory abilities, it is not surprising that parasitic birds have been subjects of much more research than have parasitic insects, even though the latter undoubtedly have many equally interesting examples of coevolved adaptations.

Coevolution between Brood Parasites and Their Hosts

Cuckoo–Host Systems

Cuckoo–host systems are much more highly coevolved than the other well-studied systems, those of cowbirds, and DNA divergence data show that they are also much older. Most cuckoo species use only one or a few host species. Some species; such as the Eurasian common cuckoo, might be called generalists when viewed over their entire ranges because they parasitize 50–100 or more host species. However, even these cuckoos are more properly viewed as specialists because they use only one to several host species in each region and individual females, or members of a gens, specialize on a single host species or several similar host species. In regions where several cuckoo species coexist, they tend to show little or no overlap in host use, which reduces competition for hosts. Most cuckoos are much less abundant than their hosts and probably have little effect on host population dynamics because they affect only a small proportion of their host populations.

Some cuckoo–host systems may have reached an evolutionary equilibrium, whereas others show strong evidence of ongoing coevolution and provide some of the strongest examples in vertebrates of microevolution that has occurred during ongoing research.

Adaptations of Cuckoos

Behavior

Cuckoos typically approach nests stealthily and may quickly drop their thick-shelled eggs onto host eggs to increase chances of breaking host eggs. Some parasitic cuckoos resemble hawks, whereas nonparasitic species do not. This resemblance or simply host recognition of cuckoos incites host aggression or may frighten hosts, and males in some species use this aggression to draw hosts away from nests. This male distraction is coordinated with and facilitates nest entry by the stealthy and drab-colored females in several cuckoo species. Nestlings of some cuckoos mimic the begging calls or plumage of host young. There is evidence that great spotted cuckoos revisit nests they have parasitized and destroy host eggs or nestlings if the parasitic egg has been removed by the host. Such a protection racket or “mafia effect” could select for acceptance of host eggs.

Cuckoos find nests by watching hosts from hidden perches and laying is synchronized with that of the hosts. Most cuckoos lay one egg per nest, except in a few species in which cuckoo nestlings do not kill those of the host. Cuckoos defend territories against other cuckoos and usually remove at least one host egg before laying one of their own.

Fecundity

Cuckoos lay 8–25 eggs per season, which is generally more than their hosts lay. Eggs are laid every other day.

Egg Adaptations

Cuckoo eggs usually mimic the coloration of their hosts' eggs. Cuckoos that parasitize many host species have individually specialized females, with each group of females or gens (plural gentes) mimicking the eggs of a single host species or a group of hosts with similar eggs. Egg mimicry is usually assumed to have arisen in response to host egg recognition and recently the first evidence of disruptive selection by the common cuckoo and one of its hosts has resulted in egg polymorphism in both species. An alternative hypothesis argues that egg mimicry evolved to keep a second cuckoo from identifying and removing a cuckoo egg from an already parasitized nest and then laying its own egg in the nest. However, it is not clear that more than one cuckoo attempts to parasitize the same host nest often enough for this to be a significant selective pressure. Most cuckoos parasitize hosts that are much smaller than themselves and have correspondingly small eggs for their body sizes. However, cuckoo eggs are usually slightly larger than those of the hosts. The few species that parasitize hosts larger than themselves do not have smaller eggs. The thick shells of cuckoo eggs may be adaptive because they reduce chances of breakage of cuckoo eggs during rapid laying, facilitate breakage of host eggs (thereby reducing competition with hosts), or make cuckoo eggs resistant to pecking by hosts. A counteradaptation to egg mimicry that some hosts have developed is variable egg types. In response, some cuckoo species have evolved an equivalent range of egg types; but hosts still seem to benefit because individual female cuckoos lay only one type and may not always parasitize a host female who lays the same type. The highly variable host eggs may also function in the context of conspecific parasitism.

Nestling and Fledgling Adaptations

Nestlings in most cuckoo species have concave backs that they use to push host nestlings or eggs out of nests. Cuckoos that parasitize larger hosts do not show this eviction behavior but can compete successfully with host nestlings because they beg more loudly and incessantly, hatch earlier, and develop more rapidly. Mimicry of host begging calls occurs mainly, but not exclusively, in species that do not evict host nestlings.

Host Defenses Against Cuckoos

Defenses Against Adults

Hosts often respond aggressively to cuckoos, but this may actually provide a cue to cuckoos about their stage of the nest cycle and the proximity of nests. Mobbing cuckoos has both genetic and learned components. One possible advantage of mobbing cuckoos is that it may trigger ejection of parasitic eggs.

Egg Rejection

Hosts reject cuckoo eggs by abandoning parasitized nests or ejecting eggs directly. Small hosts are more likely to abandon (and renest), perhaps because ejection results in the incidental breakage of some of their own eggs and is therefore costly or because they are simply too small to eject cuckoo eggs. Egg rejection is most prevalent in hosts that have a long coevolutionary history with cuckoos. These hosts, which often show fine abilities to discriminate among egg types, are species that have intrinsic characteristics that make them suitable for parasitism, such as animal food appropriate for the nestling parasites and nests accessible to adult cuckoos. Species unsuitable as hosts, such as ones that have specialized nestling diets (e.g., seeds in some finch species), have presumably never been parasitized intensely in the past and generally lack egg recognition altogether. Among suitable hosts, egg recognition is more prevalent in species that are currently rarely parasitized than in species that are currently common hosts. This trend suggests that cuckoos shift away from using suitable hosts with well-developed egg recognition. It is possible that cuckoos have a dynamic system of host usage in which they repeatedly switch from hosts with well-developed defenses only to switch back to these hosts after their defenses have declined and defenses in other hosts have increased. Such a system could result in never-ending cycles of host switches and coevolution, but it is also possible that hosts retain high levels of egg recognition for long periods in the absence of parasitism, which would force cuckoos to become increasingly more specialized. Long-term retention is indicated by high levels of egg recognition in New World magpies and shrikes, the latter of which have retained egg recognition for more than 1 million years (My). Neither of these hosts are currently parasitized by any brood parasites but are descended from Old World ancestors that are cuckoo hosts. Populations of some suitable hosts that have only recently come into contact with cuckoos have apparently undergone rapid increases in egg ejection and discrimination, apparently because they possessed some recognition even in the absence of parasitism. This possession could be due

to retention of recognition from past bouts of parasitism or to gene flow from parasitized populations of the same species.

Nestling Discrimination

Despite there being many species that have some degree of mimicry of host nestling appearance or begging calls, there are relatively few cases in which cuckoo hosts show outright rejection (i.e., removal) of nonmimetic nestlings. Recent studies indicate two hosts of little bronze-cuckoos remove the parasitic nestlings from their nests, and another host deserts nests with lone parasitic Horsfield's bronze or shining bronze cuckoo nestlings using their begging calls as cues to elicit abandonment. It is possible that nestling rejection is more widespread given the difficulty in detecting it. However, it is also possible that the selective value of nestling mimicry may also relate to ensuring that parasitic nestlings receive high-quality care from their hosts rather than avoiding outright rejection.

Cowbird–Host Systems

The five brood parasitic cowbirds include one of the most specialized of all brood parasites and the two most generalized of all brood parasites. The authors have chosen to highlight cowbird–host interactions in this article because there is a vast literature on cowbird–host systems and because these systems are quite different from cuckoo–host systems.

Cowbird Adaptations

Egg Adaptations

As described previously (*see* Icteridae), some cowbirds are extremely fecund, an apparent reflection of a trade-off between egg production and parental care. In captivity, brown-headed cowbirds can lay up to 77 eggs in the short temperate breeding season and field estimates of shiny cowbird productivity exceed 100 eggs during the much longer tropical breeding season. As in cuckoos, the eggs of the smaller cowbirds are small relative to the size of the cowbird but are larger, thicker shelled, rounder, and faster to develop than those of most of their hosts. Only the giant cowbird, which parasitizes hosts as large as itself, has normally proportioned eggs. The other smaller species usually parasitize smaller hosts. Egg mimicry has not been firmly established in any cowbirds, but cowbird egg shape and patterns have evolved, perhaps in response to diffuse selection by dominant hosts or groups of hosts. The two most generalized cowbirds, the shiny and brown-headed, have generalized spotted egg colorations that are similar to those of many passerines. Although cowbird egg coloration is not finely tuned to host egg coloration to the same degree as in cuckoos, it has undergone some shifts, presumably in response to host use, during the evolution of the cowbird lineage. Different cowbird species have generalized spotted eggs or immaculate unspotted ones; however, two species, the giant and shiny cowbirds, have both kinds of eggs. There appears to be some host specialization by female shiny cowbirds and their eggs resemble host eggs in shape and background color in at least two host species.

Behavioral Adaptations of Adults

Similar to cuckoos, cowbirds search for nests primarily by observing the behavior of hosts. Cowbirds approach nests stealthily and lay eggs very early in the morning before most hosts appear at their nests during the egg-laying period. In contrast, giant cowbirds appear to circumvent the defenses of colonial hosts by visiting colonies as a group in which males appear to distract hosts while females stealthily enter nests. Screaming cowbirds also visit their communally breeding hosts in groups, but males do not appear to help distract the hosts. Cowbird eggs are usually synchronized properly with host laying but improperly timed eggs that appear before the host eggs or after hosts have finished laying occur more commonly than in cuckoos. Although generalist cowbird species avoid parasitizing some species that are clearly unsuitable as hosts, such as doves, there is little evidence that they select the best host species in a community. Many cowbird eggs are seemingly wasted in nests of hosts that feed their nestlings inappropriate diets of seeds or fruit or that eject cowbird eggs. However, parasitism of the latter species may sometimes be adaptive for two reasons. First, some species that exercise egg recognition and ejection have low nest predation rates. Second, these species learn the appearance of their own eggs by imprinting on the first egg or eggs that they lay during their lives. Accordingly, naive hosts parasitized about the time they begin laying may come to learn cowbird eggs as their own eggs and may provide cowbirds with nests that have a relatively low likelihood of failing due to nest predation. Multiple parasitism (two or more cowbird eggs in a nest) occurs in approximately one-third of all nests parasitized by cowbirds, especially with some large hosts. Several female cowbirds sometimes lay in the same nest even though multiple parasitism usually reduces the success rate of cowbird eggs and many host nests receive no cowbird eggs. Female cowbirds are usually highly aggressive toward one another in habitats in which hosts occur (but not in which cowbirds feed), but there is still substantial overlap among home ranges. Cowbirds sometimes, but not always, remove host eggs by puncturing them. Egg removal is rarely done during the same nest visits on which females lay but may occur the afternoon before or later in the morning on which cowbird eggs are laid. Egg removal may enhance incubation of the parasitic egg and females sometimes consume the host egg. There are many observations of cowbirds depredating unparasitized host nests and there is evidence that cowbirds do this regularly to stimulate renesting, which will increase the future availability of host nests to be parasitized. However, some studies have found no evidence for this depredation–renesting hypothesis and the behavior may occur only in special circumstances. Cowbirds have also been experimentally shown to engage in “mafia” behavior in which they depredate clutches from which a previously laid cowbird egg has been removed. This behavior would greatly increase the costs of egg rejection by hosts and might slow the evolution of counterdefenses in this species.

Nestling and Fledgling Adaptations

In the specialized screaming cowbird, there is almost perfect mimicry of host plumage and vocalizations of its usual host species, the bay-winged cowbird (which is not closely related to the parasitic cowbirds despite its name). This mimicry does

not seem to be essential for nestling care but instead seems to be an absolute requirement for receiving host care after the parasites fledge from host nests. Such perfect mimicry is lacking in the other, more generalized cowbirds. However, giant cowbird nestlings have white bills, like those of their oropendola hosts. Bills turn the usual cowbird-black after the fledglings become independent. Nestling cowbirds grow more rapidly and beg more loudly than the nestlings of many, but not all, of their hosts. They have relatively large mouths and show intraspecific variation in their gape colors, unlike the majority of nonparasitic nestlings. This gape variation may relate to host use in some unknown way. There is a recent report of a cowbird ejecting a host nestling, although the ejection could have been inadvertent.

Host Defenses against Cowbirds

Preventing Access to Nests

Many hosts react aggressively to cowbirds and colonial nesting may provide protection for some hosts. Aggressive responses to cowbirds, however, may reveal nest locations to cowbirds and be counterproductive for small hosts, which may not be able to drive cowbirds away from nests. Some hosts sit on their nests when approached by a cowbird, but there are records of cowbirds pulling hosts off their nests. Some hosts reduce parasitism by nesting in cavities or in dense vegetation, but even cavity nests are often parasitized in many species.

Egg Rejection

Cowbird host species can be divided into accepters, which accept cowbird eggs, and rejecters, which abandon parasitized nests, build a new nest on top of the old nest, or, most commonly, eject cowbird eggs. Within accepter species, nearly 100% of the individuals accept cowbird eggs. Rejecter species show nearly 100% rejection, although an increasing number of “intermediate” rejecters have been described, and there is little geographic variation in a species’ responses to cowbird eggs. Birds that eject cowbird eggs either puncture them or grasp them and usually drop them at least several meters from the nest. Smaller hosts tend to puncture–eject, whereas larger hosts grasp–eject. Nest abandonment occurs most frequently when cowbird eggs are laid too early in a host’s laying cycle and when hosts are too small to eject eggs (or to eject without breaking too many of their own eggs). Nest desertion appears to be triggered by encounters at the nest between hosts and cowbirds. In nearly all host species, detection of cowbird eggs in nests does not appear to play a role in eliciting desertion, even in hosts whose eggs are highly divergent from cowbird eggs. Some hosts may begin incubating early in the morning to prevent undetected cowbird parasitism. Most species that reject cowbird eggs occur in open habitats where they may have a long co-evolutionary history with cowbirds, all of which forage in open areas in association with grazing ungulates. Hosts that eject cowbird eggs recognize their own eggs and remove cowbird eggs even if these outnumber their own eggs, unless they have misimprinted on cowbird eggs laid in their very first nest. Similar to Old World cuckoo hosts, cowbird hosts retain egg rejection behavior in the absence of brood parasitism and for long periods. Island scrub-jays, Bohemian waxwings, and great-tailed and boat-tailed grackles all reject parasitism in areas where they are not parasitized by brood parasites and have

possibly retained this behavior between 150,000 and 3 My. This supports a single trajectory model whereby hosts of brood parasites are becoming increasingly intolerant of brood parasitism. As more hosts evolve rejection, cowbirds will not be able to return to parasitizing former hosts because they retain defenses, and instead will be forced to evolve specialized adaptations, such as egg mimicry, for just a few species.

Modeling Host–Parasite Coevolution

There is little doubt that the adaptations and counteradaptations described in the section Coevolution between Brood Parasites and their Hosts result from coevolution between parasites and their hosts. Parasitic counterdefenses to host defenses must correspond to the characteristics of hosts, as in mimicry of host eggs. Thus, parasites cannot have effective defenses against more than a few hosts at any one time because hosts vary in key characteristics such as egg coloration. The traditional view therefore hypothesizes that parasites specialize on increasingly fewer hosts as a parasite–host system becomes older and more hosts evolve defenses. This view is supported by studies showing that (1) recently derived brood parasites tend to be more generalized than older species (e.g., cowbirds vs. cuckoos); (2) the costs of parasitism are often much higher than the costs of potential host defenses, which suggests that there is a continuing evolutionary arms race; (3) some systems in which hosts and parasites have only recently come in contact show either an absence or low levels of host defenses; (4) host defenses have evolved since recent contact with a brood parasite; (5) parasites have evolved egg mimicry in response to host defenses; and (6) cuckoo–host systems are dynamic as evidenced by host shifts in parasitic cuckoos. In accord with these generalizations, most Old World passerines in Africa and Eurasia, which are exposed to numerous species of an ancient group (the cuckoos), possess egg recognition. However, most New World passerines, which are exposed to a smaller and relatively younger group of parasites (the cowbirds) lack egg recognition.

The question then arises, why do so many hosts accept easily distinguishable parasitic eggs? Two hypotheses have been proposed: “evolutionary lag” and “evolutionary equilibrium.” There is a burgeoning literature by proponents of each hypothesis. The evolutionary lag hypothesis is that these accepters have not yet had time to evolve antiparasite adaptations. Acceptance of parasitic eggs by some hosts in heavily parasitized, unproductive populations may also result from gene flow from populations in areas where cowbirds are absent and reproduction is high. The lag hypothesis is clearly applicable to situations in which parasites have begun to use host species with no recent history of exposure to parasitism but may even apply to some host species with long histories of parasitism because egg recognition/rejection is a totally new feature that may be difficult to evolve. In the evolutionary equilibrium hypothesis, hosts accept parasitic eggs because of the high costs of rejection. In this scenario, parasitism is costly, but trying to reject parasitism would be even more costly, i.e., accepters are making the best of a bad situation. If the “mafia” behavior described earlier (*see* Behavioral Adaptations of Adults) by cowbirds is widespread, it would increase

the costs of rejection and might lead to an evolutionary equilibrium.

Distinguishing between lag and equilibrium has proven to be difficult. Testing either hypothesis requires measurements of the costs of rejection in species that accept, which has not yet been done effectively. Sometimes, likely costs for accepters can be estimated from similar species that eject. For example, the number of their own eggs that small ejecting hosts break when they eject cowbird or cuckoo eggs can be extrapolated to accepter hosts of similar size. These ejection costs, generally less than 0.5 host eggs per ejection, do not seem to be sufficiently high to make acceptance a more adaptive option because acceptance usually results in the loss of all the host’s young for cuckoo hosts and for small cowbird hosts. There is evidence that rejecter hosts mistakenly eject their own eggs on occasion, but it is not clear if this cost is sufficient to outweigh the demonstrable costs of egg acceptance. Equilibrium may be most likely in species for which parasitism is relatively infrequent and in which parasitic eggs are not easily ejected because of the host’s small bill size and may result in damage to the host’s own eggs, or when they resemble those of the host, which greatly increases the probability of mistakes. Nevertheless, distinguishing conclusively between lag and equilibrium will require new experimental and phylogenetic studies.

Impacts on Host Population Dynamics

Brood parasitism is undoubtedly almost always costly for individual hosts, but the extent to which brood parasites threaten host populations is much less clear. Most brood parasites have little impact on host populations, presumably because coevolutionary processes reduce the frequency of parasitism and because most parasites are much less abundant than their hosts. In Europe, for example, less than 5% of most host nests are parasitized by the common cuckoo. One brood parasite, the giant cowbird, has even been hypothesized to benefit its hosts because its nestlings remove parasitic botfly eggs from its host nestmates.

Nevertheless, brood parasites can pose threats to host populations, especially generalist brood parasites and those that have undergone recent range expansions and population increases. In a few cases, cuckoos have expanded their ranges as a result of human-caused increases of early successional habitat. In areas recently colonized by cuckoos in Japan, levels of parasitism often exceed 40%, although in most of these areas the incidence of host defenses appears to be increasing rapidly, probably because these host populations already had some level of defense before being parasitized. Such rapid development of host defenses, however, appears to be absent from hosts of the brown-headed and shiny cowbirds. Furthermore, range expansions are much more pervasive in these two generalist cowbirds than in any cuckoo species. Cowbirds have undergone enormous population increases as the result of human activities, especially those associated with cattle. As a result, many host populations with no recent history of parasitism are being exposed to massive levels of brood parasitism. For some species, especially forest-nesting ones, widespread parasitism may be occurring for the first time in

the history of the species' lineage. Parasitism levels of many forest species nesting in the midwestern US, for example, exceed 80% with most nests receiving multiple cowbird eggs. Most newly exposed host lineages lack effective defenses. Several recent studies have linked large-scale population declines of songbirds with increasing levels of cowbird parasitism. Concerns about cowbird parasitism have stimulated an enormous amount of research since the late 1980s and three major symposia have been published recently on this subject.

This increased focus on cowbirds has resulted in pressure to trap and kill cowbirds to reduce their impacts on hosts. However, host species that have declined have experienced massive loss of habitat and increased rates of nest predation in addition to increased rates of cowbird parasitism. For example, most passerine species that breed in riparian habitat in the southwestern US have declined in the past century but so too has their habitat. Dams, water diversions, overgrazing, urbanization, and exotic plants have resulted in the degradation or loss of more than 90% of the riparian habitat present a century ago in the Southwest. Even if cowbirds are not the primary cause of some or all declines, they may now be exposing some reduced host populations to additional stresses that threaten the populations with extinction. Importantly, a cowbird population can be stable or grow even as it pushes a rare host to extinction because individual female cowbirds do not specialize on single host species.

Nevertheless, it is not clear whether cowbird parasitism threatens more than a few host species. Species that are most at risk are those with small geographic ranges that are wholly included within areas that contain abundant cowbird foraging habitat (pastures, feedlots, mowed grass, and bare soil) and that cannot be rescued by emigrants from more productive populations. This list includes several endangered species that are brown-headed cowbird hosts (Kirtland's warbler, black-capped vireo, least Bell's vireo, and southwestern willow flycatcher) and many species restricted to islands in the Caribbean that have recently been invaded by shiny cowbirds (yellow-shouldered blackbird and Puerto Rican vireo).

Most species in North America have very large geographic breeding ranges that include regions in which cowbirds are rare and restricted to areas near human habitations. These refugia from cowbird parasitism tend to occur in large, unfragmented habitats that may act as "sources" of surplus host young that can recolonize populations in more fragmented habitats in which levels of parasitization (and nest predation) are often very high. In these population "sinks" in fragmented habitats, levels of reproduction may be too low to compensate for adult mortality; that is, such populations can only be sustained by immigration from source habitats. Evidence for this source-sink scenario derives from well-documented sink populations in fragmented midwestern US forests. These populations are nevertheless relatively stable, probably due to immigration from populations in large, unfragmented forests in the region in which levels of both parasitism and nest predation are very low and reproductive success is sufficiently high for populations to act as sources. Such large-scale source-sink population dynamics can slow the evolution of host defenses because most young are being produced in areas in which cowbird parasitism is rare.

Cowbird Management

Many cowbird control programs have been initiated as a result of concern regarding several endangered songbird species. Controlling cowbirds, which is easily done because their social nature attracts them into traps that contain cowbirds that function as decoys or "bait," has become a multimillion dollar a year business in the American Southwest and there are also active programs elsewhere in North America and in the Caribbean. Local control efforts, in conjunction with habitat restoration, may have prevented the extinction of several endangered host species and races, and two endangered hosts have increased in population since cowbird control began. However, control programs for two other endangered hosts resulted in no increases in the sizes of host breeding populations, even though all control programs have resulted in increases in host reproductive output. Unfortunately, even when host populations increase, cowbird control must be done every year because cowbird removal has little or no year-to-year effect on the numbers of cowbirds that occur in an area due to high dispersal by cowbirds. Therefore, most workers view cowbird control as a temporary, stop-gap measure, although a US Fish and Wildlife recovery plan for the least Bell's vireo in California advocates cowbird control in "perpetuity." Larger scale control programs, such as killing cowbirds by the millions at winter roosts, have been suggested by some workers but do not seem justified given that regional breeding season control programs are effective in eliminating nearly all cowbirds from the ranges of endangered hosts. Such large-scale killing programs may also raise important ethical issues and some workers have argued that an undue emphasis on cowbirds may detract from more productive and more long-lasting management actions such as habitat restoration.

Ecology and Social Behavior of Brood Parasites

The lack of parental care in brood parasites potentially sets them apart from most other birds in their foraging ecology, mating systems, spacing behavior, and vocal development.

Foraging Ecology

Most brood parasites have unusual diets and foraging behavior. Honeyguides eat wax, many cuckoos eat hairy and toxic caterpillars, and cowbirds prefer to forage in short grass close to ungulates such as cattle, horses, or bison. In each of these cases, either the diet of the brood parasite would be difficult for nestlings to digest (wax and hairy caterpillars) or the foraging habitat may be so ephemeral (the proximity of ungulates) that it may not be available for an entire nesting cycle. It is not known, however, if these unusual foraging ecologies were precursors of brood parasitism or if they were made possible by the evolution of brood parasitism.

Mating Systems

Mating system theory predicts that birds freed from the needs of parental care should be promiscuous. Nevertheless, avian brood parasites show a remarkable array of mating systems,

including monogamy and resource-based polygyny. This variation in mating behavior has been attributed to the diverse ways in which parasites gain access to nests (some of which require cooperation between several individuals), to the great variety of foraging ecologies of brood parasites, and to such unusual features of individual host-parasite systems as strongly male-biased sex ratios in cowbirds. In general, there have been few detailed studies of the mating systems of brood parasites. The mating system of the brown-headed cowbird has received the most study among parasitic birds and has been described as promiscuous, polygynous, or monogamous. Promiscuity has been proposed because it is a common sight to see two or more males associating with a single female. However, studies of color-marked cowbirds that enabled researchers to determine which males and females mated together and associated with one another the most have indicated monogamy. A recent DNA fingerprinting study confirmed that monogamy prevails and even found that cowbirds have fewer matings outside of their pair bonds than do most nonparasitic songbirds. Field observations show that the mate faithfulness in cowbirds is due both to males guarding females from the advances of other males and to females being reluctant to mate with males other than their usual consort. Because males outnumber females, many males do not acquire a mate. A single study demonstrated promiscuity in an area in which extremely high cowbird abundances may have made it difficult for the birds to maintain pair bonds.

In one Asian honeyguide, males defend beehives and only allow access to wax if the females mate with them. In some viduine weavers and cuckoos, males display from prominent perches and are chosen by females presumably on the basis of mate quality, which may be indicated by song elements or plumage.

Spacing Behavior

Many brood parasites defend breeding areas that are rich in hosts. At least some cowbirds and many cuckoos defend home ranges against conspecifics. However, the home ranges are technically not true territories because several males and females often occupy the same area. In areas of home range overlap, some host nests are often parasitized by several female cowbirds. Cuckoos may occupy areas that are more mutually exclusive and thus this is closer to classic territoriality. In areas of low abundance, cowbirds may occupy mutually exclusive areas and thus may appear to be territorial.

Cowbirds often breed and feed on a daily basis in different areas that can be separated by as much as 15 km. After searching for nests in the morning, cowbirds commute to feeding sites in pastures, plowed fields, and in other habitats with short mowed grass. The uncoupling of breeding and feeding areas made possible by brood parasitism allows cowbirds to select a wide variety of breeding habitats, even if there are only a few foraging sites in a region. Some cuckoos also appear to have very large home ranges. Home range size is related to a bird's body size and trophic level, with predators needing especially large areas. Although cowbirds and cuckoos are not predators of other birds, adult breeding birds are a key

resource for them, and they have home ranges similar in size to those of raptors that feed on adult birds.

Vocal Behavior

Brood parasites have provided some of the clearest examples of genetically hard-wired vocal behavior, but recent studies have also shown a key role for subsequent learning in the modification of vocalizations. Because cowbirds are raised by different species, it is not surprising that at least one of their songs, the perched song, is genetically programmed. Cowbirds, however, learn to modify this song in response to female preferences and interactions with other males and develop individual repertoires of approximately five perched song types. A second song type, the flight whistle, is almost totally learned. It occurs as discrete spatial dialects generally tens of kilometers in diameter, which are so variable that trained observers may fail to recognize as cowbird vocalizations whistles from dialects they have not yet experienced. These dialects are true examples of culture and show that considerable amounts of biodiversity within a species can be related to learned/cultural differences rather than to genetic differences. Unlike the majority of songbirds that complete their vocal development by the time they are 1 year old, male cowbirds in some regions do not master local versions of whistles and perched songs until they are 2 years old.

Vocal learning occurs among one other parasitic group. Male viduine weavers incorporate elements of their host's song into their repertoire, which presumably enables females to choose a male raised by the same host species. As such, viduine weavers show a high potential for sympatric speciation by cultural learning. Such assortative mating maintains coevolutionary adaptations such as the gape mimicry that is specific to just one host. Assortative mating is essential because gape appearance is due to paternal and maternal genes. In contrast, common cuckoo and cowbird males do not incorporate host songs into their repertoires, perhaps because egg appearance, which is essential for acceptance by their hosts, is determined solely by the maternal genotype.

CBP

Female birds sometimes lay their eggs in the nests of conspecifics. This behavior has been documented in more than 200 bird species and has also been documented in some insects and fish. Among birds, CBP is most prevalent among precocial species, such as ducks and gallinaceous birds, and among altricial species that breed colonially and/or use specialized nest sites, such as cavities. CBP is rare or absent in most songbirds, even some that are colonial, and it has been well studied in swallows.

In many cases, CBP occurs when individuals lose their nests during the laying period or are unable to obtain a territory or nest site. In these situations, individuals may be making the best of a bad situation. In some species, CBP may be an alternative reproductive strategy that increases reproductive success by spreading the risk among several nests, reducing competition within a female's own nest, and exploiting the parental care of others. Recent theoretical work suggests that CBP is a necessary

precursor to the evolution of interspecific brood parasitism. CBP is especially prominent in New World cuckoos of the genus *Coccyzus*, which tend their own nests and also parasitize conspecifics and congeners. In at least some species, such as the ostrich and some ducks, individuals may benefit from CBP because extra eggs or young dilute losses to predators.

Nest defenses against CBP parallel those used to combat interspecific brood parasitism. Hosts guard their nests, especially at high population densities in barn swallows, which may exert a significant cost of nesting colonially. Parasitic females of another swallow species, the cliff swallow, actually carry their eggs between nests. The rejection of parasitic eggs laid before the host has begun laying is a common adaptation against CBP but does not necessarily involve egg recognition. True egg recognition, in which a bird discriminates among egg types, is a rare response to CBP because it is difficult to evolve because parasitic and host eggs are similar in appearance, given that they are from the same species. Also, CBP is less deleterious to hosts than is interspecific parasitism because it does not involve adaptations for killing host nestlings or asymmetries in size and incubation period that accomplish the same end. However, egg recognition in response to CBP does occur in some birds such as ploceid weaver finches of Africa and Asia, which have extensive variation among the eggs of conspecific females. Indeed, it has been hypothesized that the extreme intraspecific egg variation of these weavers is an evolutionary response to CBP. Some species with typical amounts of variation in egg appearance may lay smaller clutches than they could potentially feed to leave room for parasitic eggs. If hosts cannot recognize parasitic eggs, then laying a smaller clutch might avoid starvation of most or all nestlings when parasitism does occur. American coots also display remarkably refined abilities to recognize conspecific parasitism, possibly even by counting eggs. Coots are indeterminate layers and rejecter females not only reject the parasitic eggs by burying them or placing them at the periphery of the nest, but they also lay the normal number of eggs, whereas acceptor females lay fewer eggs in response to the addition of parasitic eggs. CBP may actually affect population sizes. In species with frequent CBP, fitness may be reduced at high population densities, which may cause populations to be cyclic. Nests of wood ducks that are placed too close together are subject to extreme levels of CBP, which can reduce population fitness.

Conclusions and Research Needs

Brood parasitism raises fascinating questions about coevolution and conservation. Studies of brood parasitism provide some of the strongest evidence of microevolution yet documented in vertebrates. The extreme mobility of cowbirds and their potential threats to host populations illustrate the importance of landscape-level processes in conservation biology. Cowbird song development has become a model system showing that both genetic and environmental factors are important to the development of behavior in general. Despite

these and other lessons learned from studies of brood parasitism, there are many unanswered questions that are vital to our understanding of this subject.

We still have much to learn about topics such as (1) why so many hosts of the cowbird in North America accept parasitism and whether an evolutionary equilibrium can account for this seemingly maladaptive behavior (2) the frequency of recognition errors in hosts with rejection behavior, (3) reasons for the lack of widespread parasite nestling recognition by hosts, (4) the frequency of “mafia”-like behaviors and nest predation by brood parasites, (5) how brood parasites choose from available hosts, (6) whether or not cowbirds pose a significant threat to populations of widespread host species, and (7) the genetic mating systems of brood parasitism. The recent invasion of the USA by a new generalist brood parasite, the shiny cowbird, also offers an excellent opportunity to study its interactions with other cowbirds and its new hosts. There is only indirect evidence that shiny cowbirds have begun parasitizing hosts in the USA and their invasion has largely stalled. Finally, most host–parasite systems remain very poorly known, especially those of the New World cuckoos, many Old World cuckoos, and some old honeyguides. Some members of the two latter groups are so poorly known that there is no direct evidence that they are parasitic. However, they are assumed to be so because closely related species are known to be parasitic.

Glossary

Dispersal limitation The degree to which the location of an organism is constrained by the location of its parent through dispersal.

Equalizing mechanisms Biotic or abiotic forces giving rise to equal net per-capita population growth rates of individuals of different species in a community.

Local community A set of individual organisms in a region of space that is typically small, in which local speciation is assumed to have a negligible impact on community dynamics, and which may be a part of or connected to a much larger metacommunity.

Metacommunity A set of individual organisms in a region of space that is typically large and may comprise many local communities.

Spatially explicit model A model with an explicit spatial structure, so that individuals are characterized by their spatial location.

Spatially implicit model A model with limited spatial structure, and in which individuals are not characterized by an explicit spatial location.

Speciation The evolutionary process whereby new species arise in a biological system.

Species abundance distribution (SAD) The number of species in a community as a function of abundance.

Species-area relationship (SAR) The number of distinct species observed as a function of sample area.

Stabilizing mechanisms Biotic or abiotic forces that introduce a tendency for species to increase when rare, giving rise to niches and possible stable coexistence of multiple species in a community.

The neutral theory of biodiversity was introduced in its modern form by Hubbell in 2001, and has quickly become one of the most vigorously discussed and highly cited frameworks in theoretical ecology (Rosindell *et al.*, 2011). The development of neutral theory was motivated by the goals of explaining the apparent coexistence of large numbers of species in high-diversity communities, and the near-universality of certain large-scale patterns of biodiversity. Its central results characterize how the ecological processes of drift, dispersal, and speciation impact the structure of communities. This has allowed for the development of mathematically rigorous predictions for patterns like the species abundance distribution and the species-area relationship that are quantitatively consistent with patterns observed empirically in many species-rich communities. The rapid development of neutral models in the last decade has also seen the formulation of nonneutral models that retain some of the original neutral theory framework, but either refine or extend the scope of its predictions.

Introduction

The neutral theory of biodiversity is an ecological theory asserting that many observed biogeographical patterns in nature can be explained by simple models that ignore differences between species. Despite the apparently radical assumption of species equivalence, the predictions of neutral models often match empirical data. Stephen Hubbell's seminal monograph (Hubbell, 2001) on neutral theory generated a wave of creativity in community ecology, and there is now a rich assortment of theoretical tools that can be used to generate neutral predictions and compare these predictions to empirical data. This ongoing research program informs scientific

understanding of when and where neutral processes can be the key determinants of biodiversity patterns in nature.

The remainder of this introduction outlines the motivations behind neutral theory, defines neutrality and describes key characteristics of neutral models. The section History gives an overview of the history of neutral theory. The section Neutral Models describes some of the models that have been used to develop neutral theory and reviews the performance of these models' predictions against biodiversity data. The section Nonneutral Extensions looks at some extensions of these models, which have in various ways included the effects of species differences while retaining some of the predictive power of neutral models. The section The Future of Neutral Theory discusses the future of neutral theory, with a particular focus on conducting more rigorous and extensive tests of neutral predictions. The article concludes with a summary and an examination of the consequences of neutral theory for scientific understanding of ecological communities.

Why Neutrality?

The ultimate goals of neutral theory, and of community ecology more generally, are to increase scientific understanding of species assemblages and to predict or manage their future behavior. How can hundreds of different tree species apparently coexist in a single 50-ha forest plot? What processes structure species abundance distributions (SADs) and species-area relationships (SARs) at different spatial scales? What governs the temporal dynamics of ensembles of species? There are both pure scientific benefits to developing this understanding, and practical conservation and management benefits as well. At what rate will species be lost with habitat destruction?

How should conservation reserves be designed to maximize biodiversity? The development of quantitative models like neutral theory can address these questions too.

The classical ecological perspective is that species coexist through their differences: each species has its own niche, and any two species too similar in form and function compete, with only the fitter surviving. The formalization of this competitive exclusion principle and the subsequent development of niche theory have given ecologists an intuitive view of how communities are structured, often borne out by empirical evidence.

There are, however, two clear challenges to this niche-structured picture. The first is empirical: in highly diverse communities it is difficult to reconcile the number of species with the number of niches. The second difficulty is theoretical: deriving predictions for classical ecological patterns like the SAR and SAD from niche theories is not only difficult, but also seems contingent on the complexities of a given community. The remarkable similarity of these and other patterns across multiple communities has led to many statistical models, but deriving these patterns from mechanistic processes in niche-based models has proved extremely difficult. Two questions therefore motivate neutral theory:

1. Is there an alternative general explanation for species coexistence that does not rely on species occupying distinct niches?
2. Is it possible to generate quantitative predictions of biodiversity patterns (such as SADs and SARs) from a mechanistic theory?

The neutral theory of biodiversity provides possible answers to these questions. To address the first question, neutral theory steps away from the idea of potentially indefinite coexistence and toward transient coexistence, also known as co-occurrence. If observed species richness arises from a simple balance between speciation and extinction, then coexistence no longer depends on each species having a distinct role in the community. Neutral theory answers the second question directly by accurately predicting certain biodiversity patterns from simple mechanistic models. This provides evidence that similar mechanisms may be responsible for generating biodiversity patterns across different communities, despite large inter-community variation in species identities, interactions, and environmental conditions. It is important to note that neutral theory does not deny the existence of nonneutral processes; it postulates that they are not important for predicting community structure at certain spatial and temporal scales.

What is Neutrality?

A clear definition of neutrality is an essential precursor to a broader discussion of the theory. An ecological community is neutral if its dynamics are independent of species' labels. This definition can be broken down into two conditions: first, the community dynamics are symmetric at the species level, so that demographic rates are equal for all species. This condition is fundamental to the idea of neutrality and formed Hubbell's original definition. However, a definition based only on this condition includes models in which diversity is maintained by strong intraspecific negative density dependence – models that

would be considered niche models by most ecologists (e.g., Volkov *et al.*, 2005). Thus, a second condition for neutrality is that intraspecific density dependence is equal to interspecific density dependence. This means that there is no intrinsic 'rare species advantage' – a stabilizing mechanism that would differentiate the dynamics of individuals belonging to rare species from those belonging to abundant species. In effect, most neutral theories are symmetric not only at the level of species, but also at the level of individuals.

Key Characteristics of Neutral Models

Although the definition of neutrality provides an overarching guiding principle, specific neutral models are needed to generate predictions and test the theory, and the definition allows scope for substantial variation among these models. The three fundamental ecological processes that most neutral models include are stochastic drift, speciation, and dispersal. The authors give a schematic picture of a neutral model in [Figure 1](#).

Stochastic Drift

In typical neutral models, stochastic birth and death processes approximate the complex, multifaceted and typically unpredictable fine-scale processes that occur in real ecosystems. The demographic stochasticity that governs the dynamics of such models is also referred to as drift. Drift is expected to drive the dynamics of species abundances when stabilizing forces, characteristic of deterministic niche theories, are weak. Some neutral models constrain the drift process by enforcing a zero-sum rule at the community level, whereas others do not.

Speciation

The definition of neutrality does not make any reference to the fundamental ecological process of speciation, but speciation may be introduced to balance extinction arising from stochastic drift, facilitating the maintenance of diversity. Point speciation, the mode of speciation in most published neutral models, allows a small but finite probability that an individual birth event will give rise to a new species. This is a schematic representation of true speciation processes, and more recent developments have added a variety of ways to model speciation in neutral theory: 'random fission' is an analog of allopatric speciation, whereas 'protracted' speciation distinguishes incipient from well-established species.

Dispersal

Neutral models treat dispersal in different ways. Hubbell's original approach has a two-scale spatial structure (*see* Neutral Models), in which dispersal is treated as immigration from a metacommunity into a local community. In other neutral models, dispersal is modeled as a spatially explicit process, in which case it is possible to give a more realistic treatment of neutral dynamics on a contiguous landscape.

History

The intellectual heritage of neutral ecology has two distinct strands: MacArthur and Wilson's theory of island

Figure 1 Schematic diagram of the processes of birth, death, speciation and dispersal, shown on a spatially explicit lattice. The death of an individual opens a space on the lattice, which is followed by a birth event: the space is colonized by the offspring of an existing organism. In spatially explicit models, dispersal limitation constrains the likelihood that a given organism's offspring will successfully colonize the space, as a function of separation. The lattice structure here imposes a zero-sum constraint, so that the total number of individuals is fixed. Subsequent models have relaxed this zero-sum constraint, so that the total number of individuals fluctuates around a fixed average.

biogeography (MacArthur and Wilson, 1967) and the neutral theory of molecular evolution (Kimura, 1968). Conceptually, the dispersal/immigration aspects of neutral ecology come from the former, whereas the speciation and drift aspects come from the latter.

Island biogeography is a seminal conceptual framework in theoretical ecology, which aims to explain variation in species richness on islands. Island biogeography predicts that steady-state species richness arises from a balance between stochastic extinction of species on the island, and immigration of new species from a mainland reservoir of biodiversity. The theory results in an explanation of the relatively low observed species richness on islands of a given size relative to equal-sized portions of a contiguous habitat, and has inspired the development of more rigorous theory in conservation biology and

the framework for metapopulation theory. It also represents a departure from niche-based approaches to understanding community assembly. The obvious similarities between island biogeography and neutral theory are that species are treated neutrally and that random dispersal is the dominant driving force in determining local species richness. However, the dynamics of individuals are not explicitly considered in the island biogeography framework, making it difficult to go beyond species richness to make predictions for patterns that depend on species abundances.

The neutral theory of molecular evolution is the second strand of ecological neutral theory's intellectual heritage. It is also the origin of much of its mathematical framework, with species exchanged for alleles, speciation events exchanged for mutations, and stochastic drift in abundances analogous to genetic drift. The neutral theory of molecular evolution posits that a majority of evolutionary changes are due to stochastic drift of selectively neutral mutations; the neutralist–selectionist debate in molecular evolution parallels the current debate among advocates of niche and neutral approaches to community ecology.

The genesis of neutral ecology came with early attempts to synthesize these two disparate branches of biological theory (Caswell, 1976; Hubbell, 1979; Bell, 2001). More than two decades later, neutral ecology gained prominence with the publication of 'The Unified Neutral Theory of Biodiversity and Biogeography' (Hubbell, 2001), which presented mathematical and numerical analyses of spatially implicit and spatially explicit neutral ecological models and made quantitative predictions for SADs, SARs, and other biogeographical patterns. The primary focus was on a specific model that unifies local community and metacommunity scales: diversity in the metacommunity is maintained through a balance of extinction and speciation, whereas diversity in the (semi-isolated) local community is maintained through a balance of local extinction and immigration from the metacommunity (see Neutral Models).

The recent history of neutral theory has seen developments on a number of fronts. Hubbell's original model has been extensively tested, and maximum likelihood techniques have added a rigorous backbone to the estimation of neutral model parameters. At the same time, new mathematical tools have been developed to generalize the way dispersal and speciation are implemented in neutral models. Nonequilibrium field theory has provided a framework for spatially explicit neutral theory in the mathematical language of many-body physics. In addition, more biologically realistic speciation modes have generalized Hubbell's original point speciation model, with, for example, random fission speciation borrowing from fragmentation theory.

Neutral Models

Hubbell's Spatially Implicit Neutral Model

Hubbell's original formulation of neutral theory is often referred to as 'spatially implicit', because although the model is not explicitly spatial, there is a degree of spatial structure introduced through the separation of the local community from the metacommunity. The dynamics of the metacommunity operate as follows: in each timestep, a randomly

chosen individual dies and is replaced (with probability $1-v$) with the offspring of another randomly chosen individual or (with probability v) by a completely new species arising from a speciation event. The metacommunity is assumed to be unchanging on timescales relevant to the local community; the local community can then be thought of as a dispersal-limited sample from this larger, static metacommunity. In the local community, in each timestep, a randomly chosen individual dies and is replaced (with probability $1-m$) with the offspring of another randomly chosen individual in the local community or (with probability m) by an immigrant from the metacommunity.

SADs

The most extensively analyzed aspect of the spatially implicit neutral model is the SAD (Hubbell, 2001; Volkov *et al.*, 2003; Alonso and McKane, 2004). Let the probability that a species has abundance n_t at time t be $P(n_t)$. In the discrete-time formulation of the model, the metacommunity is governed by the following master equations (there is an analogous continuous-time formulation that is not presented here):

$$P(n_{t+1} = n_t - 1) = \frac{n_t}{J_M} \left\{ v + (1-v) \frac{J_M - n_t}{J_M - 1} \right\}$$

$$P(n_{t+1} = n_t + 1) = \frac{J_M - n_t}{J_M} (1-v) \frac{n_t - 1}{J_M - 1}$$

$$P(n_{t+1} = n_t) = 1 - P(n_{t+1} = n_t - 1) - P(n_{t+1} = n_t + 1)$$

where J_M is the metacommunity size and v is the speciation rate. The first equation is the probability that a species with abundance n_t will decrease by one in one timestep: the first factor on the right-hand side is the probability that an individual of the focal species dies; the second factor is the probability that the newly born individual is either a new species or the offspring of an individual not belonging to the focal species. The second equation is the probability that a species with abundance n_t will increase by one in one timestep: the first factor on the right-hand side is the probability that an individual not of the focal species dies; the second factor is the probability that a speciation event does not occur; and the third factor is the probability that the newly born individual is of the focal species. The third equation is the probability that the species' abundance does not change in one timestep, and is obtained from the normalization condition. This master equation can be solved for the steady-state SAD and the expected number of species with abundance n is given by

$$\langle \phi_n \rangle_M = \frac{\theta}{n} \frac{\Gamma(J_M + 1)}{\Gamma(J_M + 1 - n)} \frac{\Gamma(J_M + \theta - n)}{\Gamma(J_M + \theta)}$$

The composite parameter $\theta = J_M v / (1 - v)$ is referred to as the fundamental biodiversity number, and $\Gamma(x)$ is the gamma function. In high-diversity communities, a very good asymptotic approximation to the SAD is given by

$$\langle \phi_n \rangle_M \sim \frac{\theta}{n} (1 - v)^n$$

This is the log-series distribution, first proposed by Fisher as a mathematical representation of SADs. The appearance of this classic distribution in the neutral metacommunity is consistent with observations of log-series distributions in nature at large scales.

The equations governing the dynamics of the local community have a similar structure to those for the metacommunity and, while the mathematical analysis is more complicated, lead also to an analytical solution for the SAD, referred to as the zero-sum multinomial or the dispersal-limited multinomial. The key result is that the dispersal-limited multinomial resembles a log-series distribution for high levels of immigration and a lognormal distribution for intermediate levels of immigration. Again, this is qualitatively consistent with data, because lognormal-shaped SADs are ubiquitous at small scales in nature. Moreover, the neutral SADs have provided good quantitative fits to empirical SADs from tropical forest tree communities and other ecosystems. The authors show one of these fits in Figure 2, where the dispersal-limited multinomial is fitted to data from six different censuses of trees on Barro Colorado Island, Panama.

This good correspondence between neutral SADs and those from empirical data has been celebrated as perhaps neutral theory's greatest achievement. An important caveat to these successes is that they often rely on curve-fitting procedures and qualitative visual comparisons. The fitted parameters are the fundamental biodiversity number (θ) and the immigration rate (m) from the metacommunity to the local community. Multivariate techniques can quantify the probability that a given set of parameters will give rise to an observed SAD, and best estimates of parameters can then be determined from maximum likelihood (Etienne, 2007). In principle, these techniques facilitate more robust fitting exercises, but in applications to empirical data different combinations of

Figure 2 Comparison of the observed and theoretical neutral species abundance distribution of forest trees (≥ 10 cm diameter at breast height) in the 50-ha permanent plot on Barro Colorado Island. The theoretical distribution from the spatially implicit neutral model is constrained only by the observed population size, species richness and mean dispersal distance; the line was not curve-fitted to the data. Each abundance class contains species with abundances falling between the values on the tick marks on either side. Species with exactly 2^x individuals are split between adjacent classes.

dispersal and speciation rate give rise to similarly plausible SADs (i.e., the maximum likelihood surfaces have broad plateaus or multiple peaks). This suggests that even the two free parameters of spatially implicit neutral theory may overfit the SAD.

One way to address the overfitting is to estimate the parameters of spatially implicit neutral theory independently from empirical data, and methods for estimating the immigration parameter from dispersal data are now available (Chisholm and Lichstein, 2009). This approach leaves the spatially implicit model with only one free parameter, the fundamental diversity number, which can be constrained on the observed species richness. Using these methods, the spatially implicit model continues to yield a good fit to the empirical SAD from Barro Colorado Island. Another way to address the overfitting problem is to incorporate other empirical data, such as phylogenetic trees, into the fitting process (Jabot and Chave, 2009).

Beyond the SAD

It is possible to make a range of other predictions from Hubbell's original model, most of which have been less explored than the SAD, and in some cases are less consistent with empirical data.

The Species-Area Relationship (SAR) quantifies the increase in the expected number of observed species with increasing sample area, and is another classic and widely investigated pattern in ecology. Predictions of SARs from the spatially implicit model do not generally match empirical SARs at large or intermediate scales, which have most often been modeled as a power-law dependence of species richness on area.

Most previous tests of neutral theory have been based on its static predictions, but its dynamic predictions can facilitate a potentially much broader set of tests. On short timescales, species-turnover does not appear to be consistent with the predictions of neutral models (Leigh, 2007). On geological timescales dynamic predictions of neutral models also appear to be unsuccessful. Analyses based on the best fit parameters of SADs for tropical forests apparently overestimate species lifetimes, and community phylogenies are more balanced than neutral predictions (Jabot and Chave, 2009). Reconciling neutral models with these data may be possible by fine-tuning parameters, such as the immigration rate (Jabot and Chave, 2009), but it seems likely that a predictive dynamic theory will need to incorporate nonneutral mechanisms.

Alternative Neutral Models

The spatially implicit neutral model, while the focus of much research, is one member of a vast set of potential neutral models. As outlined in the Introduction, other neutral models differ from the spatially implicit model and from one another primarily in their characterization of the dispersal and speciation processes.

Spatially Explicit Neutral Models

Spatially explicit models in ecology describe the abundance and distribution of species across a spatial landscape, in contrast to nonspatial models, which describe only total

abundances. With regards to neutral theory, the advantages of a spatially explicit description are threefold. Firstly, spatially explicit models facilitate more rigorous confrontations with empirical data because the process of dispersal is treated mechanistically. This permits a more explicit parameterization of dispersal: parameters can be estimated directly from field data, whereas the more abstract immigration of spatially implicit neutral theory has most often been treated as free parameter to fit neutral predictions for the SAD. Secondly, spatially explicit models, due to their increased biological realism, can potentially provide more accurate predictions of diversity patterns. This is especially true for patterns with a strong spatial component, such as SARs and spatial scaling of SADs. Third, spatially explicit models can predict a wider range of patterns, such as similarity-distance decay relationships, which usually cannot be predicted at all from non-spatial or spatially implicit models.

The potential for more, and more accurate, predictions from spatially explicit models is promising, but in practice the increased complexity of spatially explicit models makes it difficult to derive analytical results. Some models extend spatially implicit neutral theory by including a network of interconnected local communities, and analytical results are readily obtained in this framework. But given that the locations of individual organisms are not tracked in these models, they are still not truly spatially explicit. Mathematical techniques from spatial population genetics have been successfully adapted to derive analytical results for similarity-distance decay relationships from spatially explicit neutral models (Condit *et al.*, 2002). These predicted relationships closely match empirical data from tropical forest tree communities at scales beyond the typical dispersal distance. More recently, the formalism of nonequilibrium field theory (O'Dwyer and Green, 2010) has pointed toward a more general mathematical framework for spatially explicit neutral models, and approximate analytical results successfully reproduce the classic three-phase SAR observed in nature. This three-phase relationship encompasses a linear sampling phase at small scales, an approximate power-law relationship at intermediate scales, and a linear relationship at scales beyond the typical species range. It should be noted that these techniques are still in the early stages of their development, and future improvements will need to go beyond, or justify, the approximations currently necessary to obtain analytical results.

The difficulty in obtaining analytical results for spatially explicit models has also spurred the development of simulated, lattice-based spatially explicit neutral models. Drawing on the techniques of coalescent theory in population genetics, SARs and the spatial dependence of the SAD can be simulated for a wide range of speciation rates and dispersal parameters. The resulting relationships are qualitatively (and in some cases quantitatively) in agreement with empirical data, with a three-phase SAR again emerging (Rosindell and Cornell, 2007).

Currently a major limitation with testing spatially explicit neutral models is simply a lack of appropriate data at sufficiently large scales. For instance, the tropical forest data set from Barro Colorado Island can be used to generate small-scale SARs, but intermediate- and large-scale SARs are less well determined empirically. More definitive tests of

spatially explicit neutral models are thus dependent on future advances in data collection technology (*see* The Future of Neutral Theory).

Generalizing Speciation Mode

Speciation is a key process in neutral theory. The majority of neutral models, both spatially implicit and spatially explicit, have continued to use the original point speciation mode introduced by Hubbell. This approach was inspired by the process of point mutation in population genetics, but some alternative and more ecologically realistic speciation modes have since been introduced. The primary examples are random fission speciation and protracted speciation.

Random fission is intended to describe the biological process of allopatric speciation, under which geographic changes cause a population to become separated into two parts that then diverge genetically, ultimately becoming distinct species. In terms of mathematical implementation, random fission models allow for an extant species to split into two new species, with total abundance conserved through the process. Given that random fission speciation is implemented as an instantaneous process in neutral models, it still must be considered as an effective speciation mode, rather than an accurate description of allopatric speciation. Neutral models incorporating random fission speciation (Etienne and Haegeman, 2010) exhibit SADs that are qualitatively different from those of standard neutral models, potentially providing a way to distinguish between these different speciation modes.

Protracted speciation (Rosindell *et al.*, 2010) distinguishes incipient species arising from point speciation from full species, defined to be those exceeding a fixed threshold abundance. The average lifetime of an incipient species in a neutral model is shorter than that of a fully mature species, and this leads to modified predictions of SADs and the distribution of species lifetimes. These results potentially address the discrepancies between neutral theory and phylogenetic data discussed by Rosindell, though a more complete analysis has yet to be carried out.

So far, alternative speciation modes have been incorporated only in spatially implicit models, and the parallel development in spatially explicit models is likely to present further challenges, particularly for the explicit spatial process of allopatric speciation. A deep issue is the general lack of a rigorous biological definition of speciation, which stymies attempts to estimate species lifetimes from the fossil record in a consistent and meaningful manner or to devise a speciation model that can be considered objectively realistic.

Nonneutral Extensions

As discussed, neutral theory apparently provides a good description of biogeographical processes at some spatial and temporal scales, but its predictions perform less well at others. Furthermore, there are some questions that neutral theory is not designed to directly address; for example, those relating to the impact of climate change or increased nitrogen deposition on ecological communities. Accordingly, the development of nonneutral models building on the foundation of neutral

theory has been motivated by a desire to expand both the scope and accuracy of these models.

As discussed in the Introduction, neutral models include some combination of drift, dispersal and speciation, but ignore a fourth fundamental ecological process, selection, which is essentially synonymous with niche processes in an ecological community (Vellend, 2010; Tilman, 2004). When neutral theory fails, then, a possible next step is to include some kind of niche structure, where species are selected for in different ways. There are many approaches to niche models in the literature, but, in contrast to neutral models, these are often complex, highly parameterized, difficult to solve analytically and difficult to test empirically: the general picture is a set of interacting species with differing resource requirements living on a heterogeneous landscape. A key challenge is therefore to develop models that combine the greater biological realism of niche models with the parsimony, analytical tractability and quantitative testability of neutral models: ecologists seeking to bridge niche and neutral theory must decide which niche processes to include, how to model these processes and how to test the models' predictions. This section reviews four distinct approaches to building niche structure into a neutral framework: directly incorporating negative density dependence into species demographic rates; adding species interactions in the form of nonlinearities in the basic stochastic equations describing community dynamics; modeling explicit habitat differences and environmental heterogeneity; and including species or individual-level variation driven by traits such as body size. The common feature in each of these models is that they all partially break the neutral symmetry introduced in the Introduction, but retain some symmetry in order to make the models more tractable.

The first of these four types of extension was developed by Volkov *et al.* (2005). In this approach intraspecific density dependence is introduced by allowing per-capita birth and mortality rates to be general functions of abundance. The model retains a species-level symmetry because these general functions are the same for all species; it retains a strong degree of symmetry because each species' dynamics is governed by the same rules. But it breaks neutrality according to the definition given in the Introduction, because intraspecific density dependence is stronger than interspecific density dependence, giving rare species an advantage. The central result is that this drift-selection model and the spatially implicit neutral model can both fit tropical forest SADs with similar accuracy. This again provides evidence that a single snapshot of an SAD does not provide sufficient information to distinguish different underlying processes.

More recently, Haegeman and Loreau (2010) have modeled a stochastic community with general quadratic interactions; in effect, a stochastic, multispecies Lotka-Volterra system. To restrict the set of possible interactions, symmetry is again retained at the species level: the interactions are structured so that swapping species labels makes no difference to the dynamics. When intra-specific and interspecific interactions are equal, the results of this model are very similar to those of the spatially implicit neutral model: density dependence for each species reduces to a dependence on overall community size, which in effect acts as a constant per-capita mortality rate when fluctuations in total community size are small. For the

nonneutral case in which intraspecific interactions are stronger than interspecific interactions, the model makes predictions that deviate from those of neutral theory. Although the predictions of this particular model have yet to be tested against empirical data, the theoretical results do demonstrate the general point that interspecific interactions can be important even in highly symmetric models.

A third way to build niche processes on top of a neutral framework is to differentiate groups of species according to their niche or function (Chisholm and Pacala, 2010). In the limit of strong selection, each species is assigned to one of several niches, and the species can survive only in this single niche. The neutral feature of this model is that within a given niche, species are assumed to be neutral relative to one another, so that the within-niche dynamics are then dominated by random drift. In the limit of high diversity, community patterns in this model are identical to those of neutral theory. For finite diversity, signatures of niche processes arise from the fact that maximum species abundances are constrained by niche size rather than overall community size. This yet again reinforces the notion that single snapshots of SADs are not sensitive tests of underlying processes. Perhaps more importantly, it provides an insight as to why neutral theory is a good approximation to community dynamics in high-diversity ecosystems: species can drift relative to one another even in strongly niche-structured systems, as long as the number of species per niche is sufficiently high.

Finally, O'Dwyer *et al.* (2009) have introduced fitness variation into a neutral framework by allowing individual birth, death, and ontogenetic growth rates to vary by body size. Symmetry is thus broken at the individual level but retained at the species level, because each species has the same scaling of demographic rates with body size. Empirical data from tropical forests do indeed indicate that demographic rates can vary by body size, so in that sense this model is more realistic than a neutral model. The model leads to some predictions that differ from or extend those of neutral models, but these predictions have not yet been tested against empirical data.

In the four examples above, a common theme is the breaking of neutrality but the retention of strong symmetry. The major advantage of symmetric models is that they are often analytically tractable because they have fewer parameters. A disadvantage of symmetric models is that, heuristically, they are similar to neutral models in many respects and hence lead to predictions that are often similar to neutral predictions. The choice of which symmetries to break and which to retain has so far been made in a somewhat ad hoc fashion, meaning that approaches to breaking neutral symmetry have lacked a deeper, guiding principle.

The Future of Neutral Theory

At this stage in the development of neutral theory, Hubbell's classic spatially implicit neutral model has been extensively investigated and tested, and many other theoretical developments are beginning to come to fruition. As stated in the Introduction, the two goals of neutral theory are to improve scientific understanding of species assemblages and to predict

their behavior. Looking to the future then, it will be necessary to test the predictions of neutral models more extensively in order to identify the conditions under which they do and do not provide adequate descriptions of real communities. This, in turn, will continue to motivate the exploration of more complex models. This section draws together some of the issues identified in the previous sections, and outlines some of the most promising prospects in current neutral theory research.

Testing the Theory

As mentioned earlier, neutral theory has been tested against a relatively limited range of empirical data. Although the good fits to SADs are in many cases impressive, their limitations as tests of neutral theory have been identified by a number of authors. Three directions of research promise to extend these empirical tests to provide more rigorous tests of neutral theory.

Firstly, future tests of neutral theory should encompass a broader range of spatial and temporal biodiversity patterns. Although some studies have looked at SARs, spatial correlation functions and fluctuations in species abundances over time, these studies are in the minority. One current limitation is that relatively few analytical predictions of these spatial and temporal patterns are available. Another is that the spatial and temporal scales of empirical data are typically limited for practical reasons. Future advances in this direction depend on the continued exploration of spatially explicit and dynamical neutral models, and the development of large-scale data collection techniques.

Secondly, future tests of neutral theory will be more powerful if they are based on multiple data sets and multiple types of data rather than single snapshots of particular distributions. Comprehensive tests of any stochastic model depend on an accurate empirical characterization of the full distribution of test statistics. When it is said that SADs provide insensitive tests of neutral theory, perhaps what is really meant is that single snapshots of SADs provide insensitive tests. Mathematical machinery for performing tests on multiple SADs is likely to be more widely employed as data availability increases: the development of remote sensing and other technologies will potentially provide the extensive data necessary to test and distinguish the predictions of neutral and nonneutral theories in a more satisfactory way.

Lastly, future tests of neutral theory should include predictions of data that have yet to be observed. Such tests provide much more convincing model validation than the mostly post-hoc fitting exercises that have been performed to date. One example of an analysis that extends neutral theory in the directions outlined above is the spatial scaling of SADs. If it is possible to predict SADs at multiple spatial scales from a single neutral model, it will become possible to use an empirical SAD at one spatial scale to make a neutral prediction for the SAD at larger spatial scales.

Developing the Theory

Future theoretical developments will generate new predictions that can be used to test neutral theory more rigorously.

Especially fruitful may be the nonneutral models (*see* Non-neutral Extensions) that build on neutral theory's mathematical framework. In creating such models, a particular challenge is to decide which biological processes should be included and how they should be represented mathematically. In the spirit of neutral theory, it would seem prudent to follow the general principles of parsimony and analytical tractability. The goal is not to include all available biological information but rather to distill the essence of a complex system into a few key processes and parameters that, when chosen correctly, characterize the model's behavior over broad spatial and temporal domains.

There is also a need to attain a better understanding of why neutral theory often works so well, despite its simplicity and lack of biological detail. Analogies have been drawn between neutral theory in ecology and ideal gas theory in physics: both make assumptions that are demonstrably false but lead nevertheless to large-scale effective theories that have remarkable explanatory power. But, such analogies highlight the lack of knowledge about how, and under what circumstances, neutral theory actually could emerge from more complex and realistic niche-based theories. Indeed, it is unclear what such niche-based theories should even look like. It is possible that a deep understanding of neutral theory can be derived from top-down observations, such as the ability of many species to persist on relatively few limiting resources or the inevitable low frequency of interaction of any two species in a high-diversity system.

Applying the Theory

To date, neutral theory has rarely been used to solve problems in conservation or other applied contexts. However, the field is relatively young. In terms of direct applications, neutral theory is most applicable as a first approximation to problems that involve large numbers of species with similar ecological function and in which the driver of change is habitat destruction or fragmentation. Neutral approaches will inevitably struggle to accurately predict the dynamics of an individual species, or to predict ecological communities' responses to climate change, nitrogen deposition and other processes that almost certainly require a niche perspective. But viewed as basic science, neutral theory can inform ecologists' understanding of fundamental ecological processes, thereby contributing indirectly to the solution of applied problems.

Summary

The development of neutral theory was driven by a desire to understand the maintenance of diversity in species-rich communities, and also by the need to make quantitative predictions for patterns of biodiversity. It has been extraordinarily successful in meeting these two objectives: the emphasis on transient coexistence has highlighted an alternative perspective on species diversity, previously overshadowed by the classic niche picture of indefinite coexistence. At the same time, the equalizing mechanisms that are necessary to prolong this transient coexistence lead to a set of highly symmetric

models. This symmetry has been fundamental to the success of neutral theory, as it has helped to furnish a wide range of analytical predictions. In the case of the SAD and SAR, these predictions are surprisingly consistent with empirical patterns.

Despite these successes, there remains an apparent inconsistency between neutral theory and the vast array of species differences observed by ecologists in the field. To reconcile this, it must be emphasized that neutral theory merely hypothesizes that species differences do not impact large-scale patterns – it does not state that the differences do not exist. Nevertheless, this issue highlights the need to understand precisely which features of a real, nonneutral community lead to the emergence of neutral patterns. The universality of certain large-scale patterns across different communities provides some evidence that not all the details of a nonneutral community are equally important, but the complete picture is lacking.

The limitations of neutral theory must also be acknowledged. Neutral theory is designed to answer questions that represent only a subset of the questions of interest to ecologists. Statistical patterns of species richness and abundance (e.g., SADs and SARs) have been the subject of extensive empirical and theoretical investigation for decades, but ecologists are also interested in questions that depend intrinsically on species differences and therefore cannot be answered by neutral theory. For example, neutral models cannot predict when a certain function will be lost from an ecosystem, or under what circumstances a food web will collapse. Future progress in this direction may be achieved by wedding neutral theory's quantitative, predictive approach with insights from other branches of ecological theory.

Neutral ecology remains a work in progress, and the full range of predictions of neutral models has yet to be explored. New mathematical and computational techniques are likely to accelerate progress in the understanding of both neutral models and their nonneutral extensions in the coming years. Above all, the success of this research program will rest on its ability not only to predict patterns consistent with those already observed in nature, but also to make predictions that are unexpected or unintuitive, and yet turn out to be correct.

Acknowledgments

The BCI forest dynamics research project was made possible by National Science Foundation grants to Stephen P. Hubbell: DEB-0640386, DEB-0425651, DEB-0346488, DEB-0129874, DEB-00753102, DEB-9909347, DEB-9615226, DEB-9405933, DEB-9221033, DEB-9100058, DEB-8906869, DEB-8605042, DEB-8206992, DEB-7922197, support from the Center for Tropical Forest Science, the Smithsonian Tropical Research Institute, the John D. and Catherine T. MacArthur Foundation, the Mellon Foundation, the Celera Foundation, and numerous private individuals, and through the hard work of over 100 people from 10 countries over the past two decades. The plot project is part of the Center for Tropical Forest Science, a global network of large-scale demographic tree plots.

Glossary

Adult parasite A parasite associated with a host during part or the whole of its mature phase.

Commensalism An association of animals in which one uses food supplied in the internal or the external environment of a host without affecting the host in any way.

Ectoparasite A parasite living on the surface of a host.

Endoparasite A parasite living inside a host.

Facultative parasite A parasite that can also live without a host.

Final (= definitive) host A host that harbors sexually mature stages of a parasite.

Hyperparasite (of first, second, etc. degree) A parasite living on or in another parasite.

Intermediate host A host that harbors sexually immature, developing stages of a parasite.

Intraspecific parasitism A parasitic association of members of the same species.

Latent parasitism Parasitism without obvious symptoms.

Mutualism An association of organisms in which both partners benefit from the association.

Obligatory parasite A parasite that cannot survive without a host.

Periodic parasite A parasite visiting a host at intervals.

Permanent parasite A parasite associated with a host for long periods.

Phoresis An association in which one organism uses another as a means of transport and protection.

Symbiosis (*sensu lato*) Any association between organisms (parasitism, commensalism, mutualism, phoresis).

Symbiosis (*sensu strictu*) An association of organisms in which both partners benefit from the association and cannot live without each other.

Transport host A host that harbors sexually immature stages of a parasite that do not develop.

Parasitism is defined in different ways by different authors, usually reflecting their research interest and bias. Parasitism, as used here, is defined as a close association between two organisms in which one, the parasite, depends on the other, the host, deriving some benefit (usually food) from it without necessarily damaging it. Traditionally, fungi, bacteria, and viruses, many of which are parasitic, are studied by microbiologists, whereas parasitologists study protozoan and metazoan parasites. In this contribution, only protozoan and metazoan parasites as well as higher plants (angiosperms) are included. Several types of associations resemble parasitism in various ways and cannot always be clearly distinguished from it, either because of insufficient knowledge or because genuine intermediate forms exist. Such associations are discussed in the following section.

Related Phenomena

Commensalism

A commensal is an organism that uses food supplied in the internal or the external environment of the host, without establishing a close association with the host, for instance by feeding on its tissues. Examples are the amoeba *Entamoeba coli*, an endocommensal of humans feeding on bacteria in the lumen of the intestine, and the ciliate protozoan *Ephelota gemmipara*, an ectocommensal on various marine invertebrates.

Phoresis (Phoresy)

In a phoretic association, one organism uses another as a means of transport and protection. An example is barnacles living on whales.

Mutualism

A mutualistic association is one in which both organisms derive a benefit, but the association is not compulsory. The cleaner fish *Labroides dimidiatus* feeds on parasites and diseased tissues of various marine fishes, and both partners derive a benefit, the cleaner obtaining food and the host fish getting rid of their parasites and diseased tissues.

Symbiosis

Symbionts live in a compulsory association in which both partners derive a benefit. An example is the symbiosis of fungi and algae in lichens. It should be noted, however, that the term symbiosis is sometimes used in a wider sense, including all types of associations between organisms (parasitism, commensalism, phoresis, and mutualism).

Predation

A predator is an organism that attacks another, the prey, and usually kills and eats it. Most predators are larger than their prey.

An organism may be a parasite under certain conditions, but a commensal, a mutualist, or a predator when conditions change. For example, *Entamoeba histolytica* is often a harmless commensal feeding on bacteria in the intestine of humans, but may become a dangerous parasite feeding on red blood cells, apparently induced by some changes in the host that are not fully understood. A number of normally pathogenic parasites even improve the health and fitness of their hosts at low infection intensities. Thus, Lincicome (1971, cited in Rohde, 1993) conducted some controlled experiments using rats and mice infected with two species of trypanosomes and the

nematode *Trichinella spiralis* that showed that parasitized animals grew faster, ate more, could compensate better for deficiencies in the diet, had livers richer in certain vitamins, and were more active and more responsive to the human presence. For these reasons, it is best to consider parasitism as a type of association that is not clearly delimited from the others.

Types of Parasites

There are many types of parasites, distinguished by the site of infection, kinds of hosts, state of development, etc. Ectoparasites are parasites that live on the external surface of hosts, for example, fleas and lice of various terrestrial vertebrates, and Monogenea and Copepoda of freshwater and marine fishes. Endoparasites are parasites that live in the tissues and organs of their hosts, such as tapeworms, flukes, and protozoans of vertebrates. An obligatory parasite is a parasite that cannot survive without a host, such as the malaria parasite, and a facultative parasite is a parasite that can also live without a host, such as maggots, which are normally saprophagous but can infect living hosts as well. A permanent parasite is associated with a host for long periods, whereas a temporary parasite is found in or on a host only for short periods: examples of the former are human helminths and blood protozoans and examples of the latter are mosquitoes and leeches that visit hosts for blood-sucking only for short periods. Larval parasites, like the praniza larva of isopods, are parasitic only at a larval stage, and adult parasites, to which most metazoan parasites belong, are associated with a host during part or the whole of their mature phase. Periodic parasites (leeches, mosquitoes) visit a host at intervals. Intraspecific parasites parasitize individuals of the same species; for example, males of certain deep-sea fish are permanently attached to females of the species and derive food from them. Hyperparasites (of the first, second, etc. degrees) are parasites living on or in other parasites. An example of a hyperparasite of the first degree is *Udonella*, a monogenean parasitic on copepods, which themselves parasitize marine fishes. Microparasites, i.e., protozoans, bacteria, viruses, and some helminths, are small, with short generation times; they reproduce on or in a host usually at high rates, the duration of infection is usually much shorter than the life span of the host, and they induce immune responses in vertebrates. Macroparasites, i.e., most helminths and arthropods, do not reproduce on or in the host, they have longer generation times than microparasites, immune responses are lacking or weak and depend on infection intensities, and infections are often chronic and lead to morbidity rather than mortality. Parasitoids, many species of Hymenoptera, lay their eggs into insect hosts that may survive for some time but are invariably killed by the growing larvae of the parasitoids. Hence, parasitoids are predators rather than genuine parasites.

Adaptations to Parasitism

Size of Parasites

Most parasite species are much smaller than their hosts. Malaria parasites, for example, are microscopic protozoans,

and human pinworms are less than 1 cm long. Nevertheless, some species reach a remarkable size. For example, a didymozoid trematode infecting the sunfish, *Mola mola*, reaches a length of 12 m, although its diameter is very small and the volume of the parasite is still much smaller than that of the fish, which reaches a weight of 1 ton. Likewise, the broad fish tapeworm, *Diphyllobothrium latum*, which lives in the intestine of various fish-eating mammals, including humans, reaches a length of greater than 10 m, but its volume is much smaller than that of its hosts. At first glance, perhaps surprisingly, parasites are often considerably larger than their free-living relatives. This phenomenon is clearly shown in flatworms, phylum Platyhelminthes. Most free-living flatworms are very small, from less than 1 mm to a few millimeters long, whereas parasitic flatworms such as flukes and tapeworms, as a rule, are much larger, up to several centimeters in length for the flukes and many meters long for the tapeworms. There may be two reasons for this. First, parasitic flatworms in the organs and tissues of their hosts have a much richer and consistent food supply than do free-living species, and food supply therefore does not present a limit to size. Second, selection may have favored multiple and larger gonads and, therefore, a large body size because parasites have to produce many offspring in order to overcome the hazards involved in infecting other hosts. But selection may also favor a smaller body size, because parasites depend on living hosts and it is important that hosts survive at least until the parasite has produced offspring that can infect other hosts. A smaller size of parasites relative to that of their hosts is therefore an advantage.

Reduction and Increase in Complexity

A general misconception is that all parasites have a less complex structure than free-living forms, a phenomenon that has been named sacculinization after the parasitic barnacle *Sacculina*, which infects marine crabs and which indeed shows a remarkable reduction in complexity: the only parts of the parasite visible on the outside of the host are the so-called externa, a sac-like structure containing the gonads. Most of the parasite consists of an extensive system of cytoplasmic processes reaching into the various host tissues (Figure 1). All the crustacean characteristics have been lost, and only the free-living larval stage indicates that the parasite is indeed a crustacean, related to barnacles. However, in most parasites, such a reduction in complexity has not occurred, and in many species there is, in fact, an increase in complexity. A well-studied example of the latter case is the trematode *Lobatostoma manteri*, a parasite of marine fishes, about 3–5 mm long, which not only has a remarkably complex nervous system with more longitudinal nerve cords than free-living flatworms but also about 20,000–40,000 sensory receptors, belonging to about a dozen different types distinguishable under the electron microscope (Figure 2). These numbers are much larger than those of most related free-living flatworms, and this in spite of the fact that there is not a single free-living stage in the life cycle of this parasite. The adult worm lives in the small intestine of marine fish, it produces eggs containing an infective larva, the egg is eaten by a snail in which the larva hatches and develops to a stage infective to fish, and fish become infected by eating snails.

Increase in Reproductive Capacity

Almost all parasites that have been studied produce a remarkable number of offspring, greater than that of related free-living forms. An example is given in [Table 1](#); free-living turbellarians produce the fewest offspring of any flatworms, ectoparasitic Monogenea produce more, and the highest number of offspring is produced by endoparasitic trematodes and cestodes. Most trematodes and some tapeworms not only produce large numbers of eggs, but also there is a secondary increase in the numbers of offspring in the intermediate hosts by asexual or parthenogenetic reproduction. Thus, a single egg of a trematode can produce thousands of cercariae, i.e., larval stages infective to the final, vertebrate host. A prerequisite for this increased reproductive capacity is the safe and rich food supply available to parasites as well as the relatively large body size of many parasites compared with their free-living relatives (*see* Size of Parasites). However, it is likely that selection has favored an increased reproductive output, because the hazards encountered by parasites in their often complex life cycles are enormous. Very few larvae will survive and establish an infection.

Mechanisms of Dispersal

Dispersal is important for any species, whether free-living or parasitic, because a population restricted to one small area risks becoming extinct if conditions become unfavorable and because dispersal reduces inbreeding and the loss of evolutionary adaptability. For parasites, a third point is important: dispersal may reduce the chances of hosts becoming over-infected. Three aspects of dispersal are important: dispersal

over short distances away from an individual host, dispersal in space and range extension over larger distances, and dispersal in time. Trematode larvae illustrate that all three aspects of dispersal can be brought about by the same stage. Larvae (cercariae) are often forcibly ejected into the respiratory currents of the snails in which they have developed, bringing about dispersal away from the host. They actively swim and keep afloat by means of their tails and can thus be dispersed over long distances by water currents. In many species, special flotation devices of the tail prolong the duration of floating ([Figure 3](#)). Adult flukes produce eggs, and larvae in the snail hosts are produced over long periods, months, or even many years, leading to dispersal in time.

Mechanisms of Infection

It is essential for a parasite to ensure entry into a host, and this is achieved by an amazing variety of mechanisms. [Table 2](#) lists examples of the infection mechanisms used by human parasites. Many parasite species have evolved remarkable behavioral adaptations that facilitate transmission to a host. For example, microfilariae, i.e., larvae of various species of filariae (nematodes), circulate in the peripheral blood of vertebrates, where they are ingested by mosquitoes for further development. Depending on the activities of the mosquito species involved, the microfilariae appear in the peripheral blood either during the day or the night, and strains of the same species may be nocturnal in one area and diurnal in another. Larvae of some monogeneans have endogenous hatching rhythms (rhythms not induced by external factors) adapted to the hosts' behavior. Some species (and strains) hatch in the

Figure 2 Sensory receptors of adult *Lobatostoma manteri* (Trematoda, Aspidogastrea). After Boas, redrawn from Rohde K (1993) *Ecology of Marine Parasites*, 2nd edn. Oxford: CAB International.

Table 1 Approximate estimates of fecundity of free-living and parasitic flatworms

	Number of eggs	Multiplication of larvae
Free-living Turbellaria	10	None
Ectoparasitic Monogenea	1000	None
Endoparasitic trematodes	10 million	× 1000 at least
Endoparasitic tapeworms	10 million	× 1–1000

evening and others in the morning, whenever chances to infect a host fish are greatest. Perhaps most remarkable are the adaptations of some trematodes. For example, the liver fluke of sheep, *Dicrocoelium lanceolatum*, uses terrestrial snails as the first and ants as the second intermediate hosts. Cercariae produced in the snails aggregate in slime balls inside the snails, are expelled by the snails, and are eaten by ants. The first cercariae that enter an ant migrate into the subesophageal ganglion, inducing spastic behavior of the ant, which makes it cling to a plant, where their chances of being eaten by sheep are enhanced. The trematode *Leucochloridium macrostomum* has a larval stage, the sporocyst, which forms colorful outgrowths that extend into the snail's tentacles. They pulsate rhythmically, mimicking worms, the natural food of small birds, which are the final hosts. Birds bite off the tentacles and become infected. Infection also induces snails to move to more exposed sites.

Aggregation

The distribution of organisms in space may be even (more or less equal distances between individuals), random (random distances between individuals), or aggregated (or clustered, or overdispersed; individuals occur in clusters). Applied to populations of parasites, as a rule, parasites show an aggregated distribution in host populations: some individuals are heavily infected, but most are very lightly infected or not at all. Very often, such distributions can be described best by a negative binomial distribution. The reasons for aggregated distributions are manifold: a series of exposures, each with different chances of infection; a nonrandom distribution of infective stages; an increase or decrease in chances for further infections by a first infection; variations in the susceptibility of host individuals; and changes of infection of individual hosts over time. Selection may even have favored aggregation in order to restrict damage to a few heavily infected individuals or to facilitate mating, but experimental evidence does not exist.

Hermaphroditism, Parthenogenesis, and Asexual Reproduction

Contact between parasites and hosts is usually sporadic and, in most cases, only a single or a few parasites will manage to infect a host. It is important that populations can be built up from these individuals. A single individual can produce

Figure 3 Marine cercariae with various flotation mechanisms on the tail. After various authors, reproduced from Rohde K (1993) *Ecology of Marine Parasites*, 2nd edn. Oxford: CAB International.

large populations by parthenogenetic or asexual reproduction. In the first case, gametes develop without fertilization; in the second, somatic cells develop. An example of the second case is malaria parasites developing by schizogony in human red blood cells. An example for the first case is (probably) trematode larvae developing in snails. Almost all trematodes, as well as the cestodes and monogeneans, are hermaphroditic, thereby doubling the chance of meeting a mating partner. Furthermore, some species can at least sometimes self-fertilize.

Host Specificity

All parasites are restricted to certain host species, i.e., they cannot infect all species available, although some parasite

Table 2 Infection mechanisms of some human parasites

Means of infection	Parasite
Inoculation by arthropod hosts	Malaria parasite (<i>Plasmodium</i>); sleeping sickness
Fecal contamination of wounds	Chagas disease (<i>Trypanosoma cruzi</i>)
Retrofection (through the anus into the large intestine)	Pinworm (<i>Enterobius vermicularis</i>)
Ingestion of cysts	Amebic dysentery (<i>Entamoeba histolytica</i>)
Ingestion of eggs	Roundworm (<i>Ascaris lumbricoides</i>)
Ingestion of spores	Microsporans
Ingestion of transport hosts	Anisakis
Ingestion of intermediate hosts	Broad fish tapeworm (<i>Diphyllobothrium latum</i>)
Inhalation	<i>Pneumocystis carinii</i> (likely, but no experimental evidence)
Contact transfer	Mange mite (<i>Sarcoptes scabiei</i>), lice
Kissing or joint use of eating or drinking utensils	<i>Trichomonas tenax</i>
Sexual intercourse	<i>Trichomonas vaginalis</i>
Penetration through the skin	Bilharzia (<i>Schistosoma</i> spp.); hookworm (<i>Ancylostoma</i> , <i>Necator</i>)
Penetration into the nasal passages	Primary amebic meningoencephalitis (<i>Naegleria fowleri</i>)
Intrauterine infection	Toxoplasma, malaria

species are more restricted than others. For example, the human pinworm, *Enterobius vermicularis*, is found only in humans, whereas the protozoan *Toxoplasma gondii* has been found in a wide range of mammals and birds.

Some parasites, although found in many hosts, nevertheless infect a single or a few host species much more strongly than others. It is therefore useful to distinguish host range (the number of host species infected irrespective of how frequently and how strongly they are infected) and host specificity (taking frequency, or prevalence, and intensity of infection into account). A parasite that infects many host species, but one of them much more strongly than the others, may have a greater host specificity than a parasite species that infects fewer host species, but all of them strongly. Indices to measure host specificity are available (Rohde, 1993).

Site Specificity

There is no universal parasite that infects all organs and tissues of a host equally, but the degree of site specificity within or on a host varies considerably. *Entamoeba histolytica* infects not only the intestine of humans but also the liver, lungs, brain, and other organs, whereas adult schistosomes are restricted to the blood vessels. Site specificity is extreme in many Monogenea on the gills of fishes. Different species occupy different parts of the gill on the same host (Figure 4).

Simple and Complex Life Cycles

Many parasites use a single host; i.e., they have a direct life cycle. Others use a final (definitive) host as well as one or several intermediate hosts; i.e., they have indirect life cycles. Parasites with direct life cycles include fleas and lice on various vertebrates as well as many intestinal nematodes and Monogenea on the skin and gills of fish. Usually, the adult stage is parasitic. It produces eggs or larvae that infect the same or other host individuals. In the case of some isopods, the only parasitic stage is the so-called praniza larva: adults live on the sea floor, larvae attach themselves to the gills of fish, suck blood, and drop off to mature in the benthic environment. Parasites with indirect life cycles include the trematodes, some with a single intermediate host and others with several. An example of the former is the aspidogastreaean trematode *Lo. manteri*: the adult infects the intestine of marine fish; eggs are produced and shed in the feces; they are eaten by marine snails, in which the larvae hatch and grow to (almost) adult body size; and fish become infected by eating snails (Figure 5). An example of a trematode with two intermediate hosts is the Chinese liver fluke, *Opisthorchis (Clonorchis) sinensis*. Adults infect the liver of fish-eating mammals, including humans; snails are the first and fish the second intermediate hosts. An example of a trematode with three intermediate hosts is the bird fluke *Strigea falconispalumbi*. Adults live in predatory birds, the first intermediate hosts are snails, the second intermediate hosts are tadpoles/frogs, and the third intermediate hosts are amphibians, snakes, mammals, and birds, which are eaten by the final hosts (Figure 6). The life cycles of some trematodes with four hosts can be extended by incorporating various transport hosts in which larvae accumulate but do not develop further. Nematodes with indirect life cycles include filariae, which are transmitted by blood-sucking dipterans. Some nematodes with direct life cycles include species whose larvae undergo a peculiar migration through the body of the host. The human roundworm *Ascaris lumbricoides*, for instance, produces eggs that are swallowed by the host. They hatch in the digestive tract but do not grow there to the adult stage; instead, they penetrate the wall of the intestine, invade the blood vessels, are carried into the lungs, penetrate through the alveoli, migrate up the trachea, are swallowed a second time, and now develop to the adult stage in the intestine. The reasons for this curious phenomenon are not known, but it may reflect a different kind of life cycle in the evolutionary past. Hookworms, which infect their hosts by penetrating through the skin, undergo a similar body migration involving passage through the lung alveoli and final maturation in the intestine.

Some Physiological Adaptations

Parasites belong to a wide range of taxa and infect a wide range of hosts. Hence, their physiological adaptations are also diverse and cannot be discussed in any detail here. Jennings (in Rohde, 1997) has carried out detailed comparative studies of free-living, ecto-, and endoparasitic flatworms. These studies are particularly informative because they show the transition from free-living to commensal to ecto- and endoparasitic forms. Some free-living turbellarians living on the body surface and in the gill chambers of their hosts feed on the same kind of food as their free-living relatives, but in addition, they

Figure 4 Monogenean gill parasites on the gills of mackerel, *Scomber australis*, off southeastern Australia. P, pseudobranch; 1–4, gills 1–4; ext, external gill filaments; int, internal gill filaments. A, *Kuhnia sprostoni*, B, *Kuhnia scombr*, C, *Kuhnia scombercolias*, D, *Grubea australis*; x, *Pseudokuhnia minor*. Note that species A–D have identical copulatory organs, and species x has different copulatory organs; A–D are spatially segregated from each other, and species x overlaps with B–D.

also feed opportunistically on food scraps of the host. Food reserves and digestive physiology do not differ from those of free-living species. Turbellarians living in the interior of mollusks, arthropods, and echinoderms have become increasingly dependent on their hosts. Some feed on protozoans also

Figure 5 Life cycle of *Lobatostoma manteri* (Trematoda, Aspidogastrea). Note one intermediate (snail) and a final host (fish). No multiplication of larvae occurs in the intermediate host.

found in the hosts as well as on food ingested by the host, intestinal cells, and coelomocytes. Others feed mainly on intestinal cells, using some digestive enzymes from the host, and others entirely lack digestive enzymes and depend on enzymes ingested with host tissues. Most of the endoparasitic turbellarians do not store lipids (as free-living and ectocommensal forms do), but they store glycogen instead. Glycogen storage is also characteristic of the Neodermata (the major groups of parasitic flatworms, including the Monogenea, Trematoda, and Cestoda). Some endoparasitic turbellarians possess physiologically active hemoglobin, which allow preferential abstraction of oxygen from host tissues.

Adaptations of Flowering Plants

Parasitic plants have haustoria, which form a close connection with the vascular system of host plants, either in the roots or in the shoots. They depend entirely or partly on the host for water and inorganic and organic solutes. Hemiparasites, i.e., plants only partly dependent on the host, have chlorophyll, whereas holoparasites, i.e., plants entirely dependent on the host, lack chlorophyll.

Origins of Parasitism and Complex Life Cycles, The Evolution of Virulence, and Coevolution of Hosts and Parasites

Origins of Parasitism and Complex Life Cycles

Few fossil parasites are known. They include schistosome eggs from ancient Egyptian mummies a few thousand years ago and galls on the arms of feather stars, probably produced by

Myzostomida (parasitic annelids) from the Silurian and Devonian periods, 350–430 million years ago (Ma). Conclusions on the origins of parasitism and parasite life cycles must therefore be based on inferences from comparative studies of extant species. The Platyhelminthes have been studied most thoroughly, using DNA studies of several genes, in particular 18-S rDNA and 28-S rDNA, and phylogenetic systematics (cladistics). Phylogenetic systematics seeks to establish branching patterns in phylogeny on the basis of shared acquired characteristics (synapomorphies). Ultra-structural characteristics are of particular use because of their complexity. Cladistic and DNA studies by many authors have consistently shown that the Neodermata, the major groups of parasitic flatworms (Trematoda, Monogenea, and Cestoda), all share a common ancestor, i.e., are monophyletic. The Neodermata, or the Neodermata plus some of the parasitic turbellarians, are the sister group of a very large taxon, including most Turbellaria, with which they share a common ancestor. This means that the parasitic groups evolved very early in evolutionary history. Among the Neodermata, the trematodes are the sister group of the other Neodermata and, among the trematodes, the Aspidogastrea are the sister group of the other trematodes or Digenea. Three of the four families of Aspidogastrea occur in elasmobranchs, whereas almost all digeneans parasitize teleost fishes, amphibians, reptiles, birds, and mammals; very few species of Digenea have been recorded from elasmobranchs, to which they have secondarily adapted. Fossil records indicate that elasmobranchs are 450 My old and teleosts are 210 My old. This suggests that the Aspidogastrea are the oldest extant trematodes and possibly neodermatans. It also suggests that the simple life cycle of Aspidogastrea (Figure 5) is the original life cycle of trematodes, including a final and an intermediate host (which, in some species, is not obligatory),

Figure 6 Life cycle of the trematode *Strigea falconispalumbi*. Note: Final hosts (predatory birds) containing adult worms that produce eggs in which miracidia develop, first intermediate host (snails) containing the sporocysts that produce cercariae, second intermediate host (tadpoles/frogs) containing mesocercariae, and third intermediate hosts (amphibians, snakes, birds, mammals) containing metacercariae. Modified from Odening K (1969) *Entwicklungswege der Schmarotzerwürmer*. Leipzig: Akademische Verlagsgesellschaft Geest & Portig K. G. © Spektrum Akademischen Verlag, Heidelberg, Berlin, with permission from Wiley.

without multiplication of larval stages in the intermediate host. The complex life cycles of digenean trematodes, including a final and at least one, and up to three, intermediate hosts and several transport hosts, with multiplication of larval stages in the first intermediate host (Figure 6), may have evolved from this primitive kind of life cycle to make transmission to the final host more effective.

Among the crustaceans, most barnacles are free-living, attached to rocks or other hard substrata. Some barnacles live in a phoretic association, for instance with whales, attached to their skin and feeding on plankton in the environment. Other, closely related species have become parasites. Thus, *Anelasma* parasitizes the skin of sharks, processes of its stalk branching in the host's muscles and extracting food from it. All the approximately 120 species of rhizocephalans, also related to the barnacles, are parasites and strongly modified in adaptation to their way of life (see, e.g., Sacculina, Figure 1). This suggests that parasitism in the barnacles may have evolved from free-living to phoretic to parasitic.

Evolution of Virulence

Intuitively, one might suspect that it is not in the parasite's interest to severely damage or even kill its host, because this would also affect the fitness of the parasite. However, parasite transmission to another host may well be facilitated by such damage to an intermediate or a transport host. In other words, evolutionary pressure may have led to an increase in virulence in some cases and to a decrease in others. Anderson and May have developed an epidemiological model that considers virulence, as follows: $R_0 = \beta(N)/(\mu + a + v)$. R_0 is the fitness of the parasite, its lifetime reproductive success; β is the rate of transmission of the parasite by its host to other hosts, which is dependent on host density N ; μ is the mortality rate of uninfected hosts; a is the virulence or the mortality rate induced by the parasite; and v is the recovery rate of the host. This model (applied and further developed by various authors) allows some predictions on the evolution of virulence under different conditions. For example, a parasite that can achieve a large increase in the transmission rate by a small increase in virulence should have lower optimal virulence than one that achieves less by such an increase. The transmission rate depends, among other factors, on the likelihood of transmission for instance facilitated by the behavior of the host. Low virulence will evolve when contacts between hosts and thus opportunities for transmission are frequent. High virulence may evolve in vector-transmitted infections, and optimal virulence may differ in parasites that are vertically transmitted (from parents to offspring) from those that are horizontally transmitted. Although the parameters in the model are difficult to measure, some of the predictions have been verified empirically. Thus, parasites transmitted by contact (e.g., lice) are usually less virulent than those transmitted by vectors (e.g., malaria), and sexually transmitted parasites (e.g., *Trichomonas vaginalis*) are usually less virulent and longer lasting than parasites transmitted in other ways. In vertically transmitted nematodes of fig wasps and in vertically transmitted microsporans of mosquitoes, virulence is less than that in horizontally transmitted related species.

Coevolution of Hosts and Parasites

The comparison of phylogenetic trees of hosts and parasites has yielded contradictory results concerning possible coevolution. The reasons may be biological differences between the groups studied or they may be due to different interpretations of the results by different authors. For example, according to several authors, chewing lice infecting rodents of the family Geomyidae, as well as lice of seabirds, seem to have coevolved closely with their hosts. In contrast, lice of rock wallabies in Australia, apparently, have switched hosts frequently and there is little evidence for coevolution. Altogether, there is insufficient knowledge indicating how common coevolution is.

Host-Parasite Interactions

Cleaning Symbiosis

Hosts use a variety of behavioral methods to rid themselves of parasites. Preening of birds, bathing of birds in dust and water,

and passive and active anting (letting ants passively crawl over the body or actively squeezing ants over the plumage, respectively) are thought to help in reducing parasite loads, although evidence is scarce. Some other behavioral patterns (dolphins rubbing against rocks, fish jumping out of the water, etc.) may also play a role. Most widely distributed and well studied, particularly in the marine environment, is cleaning symbiosis, in which one animal (the cleaner) cleans another (the host), removing its parasites and diseased tissues. Birds remove ticks and other ectoparasites from cattle, hippopotamus, and even large marine fish floating on the surface, and several species of shrimps, as well as greater than 100 species of fish, are cleaners in freshwater but mainly in the sea. Besides fishes, the Galapagos marine iguana, whales and dolphins, invertebrates, etc. are hosts to cleaners. Cleaner fish often have special morphological adaptations, such as a terminal mouth and fused anterior teeth and conspicuous color patterns, the so-called guild signs. In addition, the Indo-Pacific cleaner wrasse, *L. dimidiatus*, performs a cleaning dance that attracts host fish. Hosts, on their part, show invitation postures signaling to the cleaner that they are ready to be cleaned, and fish of many species, usually hostile to each other, queue peacefully up at cleaning stations (territories where cleaning occurs). They even allow cleaners to enter their mouth cavity. In well-established cleaning symbioses, hosts rarely or never eat cleaners. Some fish were observed to spend as much time at cleaning stations as they spend on feeding, and some cleaner species feed exclusively on parasites and diseased host tissue. Certain fish mimic the color pattern and behavior of cleaners to approach hosts in order to attack them and bite off pieces of the fin or skin.

Immune and Tissue Reactions, Resistance

Defense reactions to parasites at the humoral and tissue levels are based on the ability of the host to distinguish self (its own cells) from nonself (foreign cells and material). Vertebrates have three types of such reactions: phagocytosis, inflammation, and adaptive immunity. The first two are nonspecific tissue reactions and the third is specific to a certain type of nonself material. They are found in all vertebrates, but (particularly immunity reactions) are best developed in birds and mammals. All three defense mechanisms usually interact and occur in most tissues and organs. Typically, the reactions occur in a certain sequence: degeneration or necrosis of cells due to the infection leads to an inflammatory response with edema (swelling of tissue). Phagocytic cells engulf small parasites, but if parasites are not eliminated, a chronic inflammation develops, leading to a connective tissue capsule around the parasite; macrophages in the capsule engulf damaged cells and often the parasite. Special defense mechanisms are active on the surface. Thus, fish continually shed mucoid material from the skin even if uninfected, but in infected fish, the slough increases and leads to the removal of monogenean and other ectoparasites.

Immune reactions are induced by antigens of the parasite that lead to the formation of specific antibodies in the host. In microparasites (protozoans and some helminths, e.g., *Strongyloides stercoralis*, but particularly in bacteria and viruses,

which are not discussed here), immune responses are more effective than in macroparasites (most helminths and arthropods), where they are either lacking or only short-lasting. Immune responses have been particularly well studied in trypanosomes. The antigen is a surface glycoprotein that completely covers the parasite. The host's antibodies eliminate most parasites, but a few trypanosomes of different antigenic types survive and build up a new population. This is repeated over and over again, leading to marked fluctuations in infection intensities. The host finally dies, because the immune reactions are not sufficient to destroy the entire parasite population. The number of antigenic types is very large and apparently limited only by the host's life span: more than 100 types were shown to develop in a single clone strain. In parasites with complex life cycles, such as the malaria parasite, each stage in the life cycle has different antigenic properties, and there are many variants because of the large numbers of daughter cells produced by schizogony. These are the reasons why attempts to develop effective vaccines have failed so far.

Invertebrates, apparently, cannot acquire specific immune responses; they rely on phagocytosis and capsule formation. Pearl formation in bivalves, for example, is the result of encapsulation of foreign bodies.

Hosts show different degrees of resistance to infections that are not due to acquired immunity. For example, some sheep may be less susceptible to nematodes than others because of their genetic makeup, and individuals of the same species of different ages may differ in susceptibility. Older individuals are often less infected than young ones, a phenomenon referred to as age resistance. For example, the cestode *Austramphilina elongata* uses turtles as final and crayfish as intermediate hosts, but only young crayfish can be infected experimentally: the cuticle of older individuals prevents successful penetration of the larva.

Effects on Host Individuals and Populations

There is a huge variety of effects on host individuals, depending on the parasite and host species, site of infection, virulence of parasites, and susceptibility of hosts. A few examples of human parasites may illustrate this. The mite *Demodex folliculorum*, intestinal nematodes at low infection intensities, *Toxoplasma*, etc. often do not cause symptoms. However, *Toxoplasma* and the nematode *Onchocerca volvulus* can lead to blindness and filariae can cause elephantiasis, a sometimes enormous swelling of the scrotum, legs, arms, etc. Malaria causes a range of symptoms from influenza-like to death. Hookworms, depending on the infection intensity, can cause severe anemia and death. Cysticerci of *Taenia solium*, infecting the brain, may lead to epilepsy-like symptoms and death. Nematodes of sheep often cause death, and monogeneans may severely damage the skin, fins, and gills of fish, particularly in aquaculture. Larval trematodes often cause partial or complete castration of their snail hosts, and they sometimes induce gigantism in the snails, i.e., a markedly larger body size of infected than uninfected snails.

Models predict that microparasites should be highly effective in controlling host populations, and this is indeed often the case. For example, trypanosomes and malaria

severely affect human populations and the former also affect livestock, and oyster beds were decimated by various protozoan parasites in several countries. However, almost all such reports deal with populations in abnormally high densities (humans, oysters) or with populations affected after the introduction of a parasite into an area where it was not present originally or after the introduction of a host species into a new area (livestock in Africa). The same applies to macroparasites. Host populations, under natural conditions, may sometimes be severely affected by macroparasites, but evidence is usually circumstantial and mass mortalities may not be due to parasites alone, but due to synergistic effects involving, for instance, environmental degradation, as well as parasites. Best documented are cases of mass mortalities caused by parasites in livestock and aquaculture, as well as after the introduction of parasites or hosts into a new habitat. Of historical interest is an epizootic caused by the liver fluke *Fasciola hepatica*, which caused the death of 3 million sheep in Great Britain in 1879/1880 and led to the clarification of the life cycle of this parasite. A well-documented case of an epizootic due to the introduction of a parasite is that of the monogenean *Nitzschia sturionis*, which was introduced into the Aral Sea with sturgeon from the Caspian Sea in the early 1930s. It devastated the local sturgeon population and led to the collapse of the sturgeon and caviar industry in the Aral Sea in 1937, which did not recover for 20 years. Recently, the first experimental proof was provided showing that a gastrointestinal roundworm can indeed regulate wildlife populations of red grouse in England.

The Ecological Niches of Parasites

The Niche Concept: Niche Dimensions of Parasites

A niche is defined as the total of an organism's relations to its biotic and abiotic environment. These relations define the organism's place in nature or, in ecological jargon, its place in a multidimensional niche space. Important niche dimensions of parasites are hosts, microhabitats, geographical range, sex of host, age, season, and food. Different parasite species use

different host species and different microhabitats within or on the host. Thus, particular nematodes of the cat use different microhabitats (Table 3), and even within each microhabitat, there is further subdivision, some species using certain parts of the small intestine, the stomach, etc. Male lambs in the USA have more nematodes of certain species than females, and many parasites prefer hosts of a certain age, occur only at certain seasons, or are restricted to host populations that use certain food.

Saturation of Niches with Parasites

An important question in ecology is whether habitats are saturated with species or whether empty niches exist. The most extensive and intensive studies were carried out on parasite communities on the heads and gills of marine fish. Results on 112 host species showed that the maximum component species richness was 27 parasite species but that most species had less than six (Figure 7). Similar differences were found for abundances (intensities of infection with all parasite species), which ranged from less than five for most host species to greater than 3000, with no apparent signs of damage in the most heavily infected fish. This strongly suggests that most fish species, at least, could accommodate more parasite species and individuals, and even in fish with the greatest parasite species richnesses and abundances, some parts of the gills that are occupied in other species were not infected.

Proximate and Ultimate Causes of Niche Restriction

Proximate causes are physical and chemical factors determining niche selection of a parasite, whereas ultimate causes refer to the biological function of niche selection: why has selection favored one niche over another? There are many proximate causes responsible for niche selection of different parasites, although they have been poorly studied. Parasite larvae, for example, may use chemical stimuli to locate a particular host and, even if they can infect many hosts, they may survive only on the correct ones because a factor or factors produced by the wrong hosts may kill

Table 3 Nematodes of the cat: sites of infection

Site	Species of nematode
Kidney	<i>Dioctophyma renale</i>
Colon	<i>Strongyloides mystax</i> , <i>S. tumefaciens</i> , <i>Trichuris campanula</i>
Stomach and small intestine	<i>Abbreviata gemina</i> , <i>Ancylostoma braziliense</i> , <i>Gnathosoma spinigerum</i> , <i>Mastophorus muris</i> , <i>Ollulanus tricuspis</i> , <i>Physaloptera brevispiculum</i> , <i>P. felidis</i> , <i>P. pacitae</i> , <i>P. canis</i> , <i>Rictularia cahirensis</i> , <i>Soboliphyme baturini</i> , <i>Spirura rytipleurites</i> , <i>Toxascaris leonina</i> , <i>Toxocara canis</i> , <i>T. mystax</i> , <i>Trichinella spiralis</i> (adults), <i>Uncinaria stenocephala</i> , <i>Ancylostoma tubaeforme</i> , <i>Physaloptera praeputiale</i>
Skin	<i>Dirofilaria repens</i>
Lungs	<i>Aelurostrongylus abstrusus</i> , <i>Anafilaroides rostratus</i> , <i>Capillaria aerophila</i> , <i>Troglostrongylus subcrenatus</i> , <i>Vogeloides massinoi</i> , <i>V. ramanujacharii</i>
Heart	<i>Dirofilaria immitis</i>
Middle ear	<i>Mammomomgamus auris</i>
Spinal cord	<i>Guretia paralysans</i>
Lymph vessels	<i>Brugia malayi</i>
Diaphragm and other striated muscles	<i>T. spiralis</i> (juveniles)

Figure 7 Number of ectoparasite species per host species (a) and abundances (b) of infection on 112 teleost species (5666 fish). them. Exsheathment and development of parasite larvae of different species may depend on different stimuli, redox potential, and pH in different parts of the intestine, thus determining microhabitat differences. Males and females of a host species may simply acquire different parasites because of different feeding habits, etc. Ultimate causes may be extrinsic, due to interspecific effects, or intrinsic, due to intraspecific effects. Among the interspecific effects, interspecific competition is generally considered to be the most important one, as evidenced by the occasional exclusion of one species by another, microhabitat shifts in the presence of other species, etc. However, altogether, evidence is scarce. Many cases of microhabitat differences that have been explained by interspecific competition are likely to be the result of reinforcement of reproductive barriers. Thus, only those monogeneans that have identical copulatory organs are spatially segregated in different microhabitats, whereas species with dissimilar copulatory organs coexist in the same microhabitat (Figure 8, also Figure 4), suggesting that

microhabitat segregation does not have the function to avoid competition but hybridization between closely related species. Only one intrinsic factor has been suggested: facilitation of mating. Many parasites live at low infection intensities and prevalences (Figure 7). Restriction to certain hosts and microhabitats may therefore vastly increase the chances of meeting a mating partner. Experimental evidence, however, is scarce.

The Structure of Parasite Communities

Concepts of Community Ecology

Community ecology deals with the relations between organisms in a certain habitat, in the case of parasites with relations between parasites infecting a certain host. Such relations can be studied at different levels, the level of infracommunity, component community, and compound community.

Figure 8 (a, b) Copulatory organs of two species of the monogenean *Kuhnia* inhabiting different parts of the gills of mackerel, *Scomber* spp. (c–e) Male and female copulatory organs of three species of the monogenean *Lamellodiscus* inhabiting the same parts of the gills of bream, *Acanthopagrus australis*. Reproduced with permission from Rohde K (1993) *Ecology of Marine Parasites*, 2nd edn. Oxford: CAB International.

Infracommunities of parasites consist of all the infrapopulations within a host individual. Component communities consist of all infrapopulations within a host population, and compound communities consist of all parasite communities within an ecosystem. An infrapopulation is the total of all the individuals of a parasite species within a host individual. Two of the major questions of community ecology are (1) whether communities show predictable patterns of species composition, relative abundances, and resource use and (2) what processes are responsible for the patterns. Studies of endo- and ectoparasite communities of various vertebrate hosts have led authors to distinguish interactive communities, characterized by species regularly occurring in huge densities with much interaction (interspecific competition) between them, and isolationist communities, characterized by species occurring at low densities with little interaction between them. Both types, supposedly, are extremes at the ends of a spectrum, with many intermediate kinds of communities between them. Authors also distinguished between core and satellite parasite species, the former dominant species with high prevalences and intensities of infection and the latter with low prevalences and intensities of infection.

Empirical Evidence

Even in host species with extremely species-rich parasite communities, core and satellite species usually cannot be

distinguished, and evidence indicates that many more parasite species than actually present could be accommodated (i.e., that vacant niches exist). This, and the frequency of positive and the scarcity of negative associations between species, scarcity of nestedness, greater intra- than interspecific aggregation, and no or only minor effects of the number of parasite species on microhabitat size, strongly suggest that interspecific competition is not of great importance. Concerning the structure of communities as indicated by predictable co-occurrence and the relative abundance of species, studies of ectoparasite communities of marine fish showed that the most dominant species usually represented between 60% and 80% of all parasites in an infracommunity but that different species were dominant in different infracommunities. For communities of larval trematodes in snails, Sousa (see Rohde, 1993) has shown that there is a significant difference between communities studied at different scales. Interactions are important at the infracommunity level, but at the level of component community, interactions are not important and communities are largely structured by external processes.

Parasite Communities as General Ecological Models

The vast majority of animal species are probably arthropods parasitizing plants, and they share many characteristics with parasites of animals: their habitats are resource-rich and seldom exhausted by the parasites. The major problem for such parasites is not to avoid competition with other species but to find the appropriate hosts and sites for feeding and mating. The conclusions based on the study of parasites of animals can therefore be applied to them.

Parasite Population Dynamics

Concepts of Population Growth

Population growth is described by the logistic growth equation $dN/dt = rN[(K - N)/K]$. dN/dt is the rate of population growth, N is the number of individuals at the time t , r is the *per capita* rate of natural population increase, and K is the carrying capacity of the habitat (the maximum number of individuals a habitat can support). The equation shows that population growth is exponential when population density is small and that it decreases with increasing N and approaches 0 when N approaches K . In a graphic representation, the curve becomes asymptotic, i.e., it flattens out when population density reaches the carrying capacity. In habitats in which, for example, populations repeatedly become impoverished as a result of external disturbances, species will be favored that can reproduce and develop rapidly, without huge investment in the individual offspring. In stable habitats where population size is usually close to the carrying capacity, it pays off to have few but well-adapted offspring. Selection for large numbers of fast-developing offspring is referred to as *r*-selection, whereas selection for few well-adapted offspring is referred to as *K*-selection. However, the general applicability of this distinction has been questioned because population density is only one of the factors that determine selection pressure.

Nevertheless, the distinction is still useful as an approximation to the real scenario.

Ecological Strategies of Parasites

Most parasites rely on the production of many offspring and therefore tend to be r-strategists. In some cases, numbers are controlled by abiotic factors and not by population size; i.e., the factors are density independent. This has been demonstrated for some helminth species, for example, the cestode *Bothriocephalus acheilognathi* in the freshwater fish *Gambusia affinis*, whose prevalence and intensity of infection varied strongly with water temperature over several years in a lake in North Carolina. However, few such studies have been conducted and generalizations are therefore premature. Density-dependent factors, i.e., factors dependent on the population size of the parasite, also play a role in some cases. For example, predation by trematode larvae in snails on other trematode larvae, immune responses of hosts that depend on infection intensities (as in many helminth infections), and competition between parasites of the same and of different species are such density-dependent factors. There is experimental evidence for all of these, but studies are too few to allow generalizations on how important such effects are. For example, high infection intensities often lead to stunted growth and a reduction in the number of offspring, an example of intraspecific competitive effects. The microhabitat of a parasite species may shift or become smaller if other species are present, or one parasite species may reduce the numbers of another or even completely eliminate it, examples of interspecific competition. However, the importance of interspecific competition, in particular, generally seems to have been overestimated.

The Diversity of Parasites (Distribution of Parasites in the Animal and Plant Kingdoms)

The first estimate of the total number of parasite species in a fauna was made by Arndt in 1940. He counted 10,000 parasitic species among the total of 40,000 species in Germany but did not include insect herbivores closely associated with plants and therefore, according to our definition, parasitic. Price, in 1977, including such species but excluding temporary parasites such as mosquitoes and leeches, estimated that more than half of all British species are parasitic. Parasites, because of their small size, are less well known than free-living forms, and this applies especially to parasites of invertebrates, which have been little studied. Estimates of parasitic species may therefore well be too low. However, recent studies of the fauna of tropical rain forest canopies have revealed an enormous number of insect species and we do not know how many of these are parasitic. There are no studies of parasites of these insects. Hence, even approximate estimates of the proportion of parasitic species are premature, although we can state with confidence that parasitism is by far the most successful way of life on earth.

Data in Table 4 show that 13 large taxa (phyla, subphyla, or classes), some of them are very large, consist entirely of parasites, and many other groups include a high proportion

of parasitic species. Even some vertebrates are parasitic. Males of a number of deep-sea fishes parasitize females of the same species (Figure 9). The needle fish, *Carapus acus*, feeds on the viscera of sea cucumbers, which represent an almost inexhaustible source of food because they regenerate, cleaner mimics (fish that mimic genuine cleaners) approach fish and bite off pieces of the fin or skin, and gulls were observed feeding on the flesh of whales. Cowbirds and about 50 species of cuckoos are brood parasites; i.e., they lay their eggs into the nests of other birds, which then incubate them. Skuas and frigate birds chase other birds in flight and feed on their regurgitated food (kleptoparasitism). Kleptoparasitism in its various varieties is widespread among humans.

Concerning plants, estimates are that 1% of flowering plants, about 3000–4000 species, are parasitic. Parasitism has evolved at least eight times in the angiosperms, and 16 plant families have parasitic species.

Zoogeography of Parasites

Latitudinal Gradients in Species Richness and Abundance

The most dangerous parasites of humans are found in warm countries: malaria (originally also found in temperate countries such as those of northern Europe), filariasis, guinea worm, sleeping sickness, Chagas disease, and several other diseases are restricted to tropical–subtropical countries. However, latitudinal gradients in species richness have been quantified best for parasites of marine fishes. Species number of marine fishes is greatest in the tropics. Species richness of metazoan ecto- and endoparasites also increases toward the tropics. However, interestingly, both the number of ectoparasitic species per host fish (their relative species richness) and their abundance increase at lower latitudes, whereas this trend does not exist for the endoparasites (Figure 10). The reasons for these differences are not understood.

Latitudinal Gradients in Reproductive Strategies

Such a gradient has been studied only in marine Monogenea. Most monogeneans produce eggs in which ciliated larvae (oncomiracidia) develop; one family, the Gyrodactylidae, consists exclusively of small viviparous species. Whereas gyrodactylids are very rare in warm waters, they represent the vast majority of all species in cold waters (75–89% in the Bering, White, and Barents Seas). This corresponds to a trend in marine benthic invertebrates, which produce large numbers of eggs from which pelagic larvae develop in warm waters and small numbers of larvae by viviparity, etc. in cold waters (Thorson's rule).

Latitudinal Gradients in Host Ranges and Host Specificity

Such trends have not been studied and are not obvious in terrestrial and freshwater parasites. Studies of trematodes and monogeneans of marine fish have shown that the former have greater host ranges, i.e., they use more host species, in cold than in warm waters, whereas monogeneans do not show such a trend, using very few hosts at all latitudes. Host specificity

^aGroups that consist entirely of parasitic species are printed in bold. After various authors. Only extant species are included.

^bMany authors refer to many of the plant-parasitic insects as herbivorous insects.

Figure 9 Intraspecific parasitism of vertebrates. Three males of the deep-sea fish *Edriolychnus schmidti* fused to a female. Reproduced from Rohde K (1993) *Ecology of Marine Parasites*, 2nd edn. Oxford: CAB International.

(i.e., the number of host species infected taking the prevalences and intensities of infection in different host species into account) is the same at all latitudes for both groups.

Parasites as Biological Markers

Parasites are frequently used as biological markers to study host populations and migrations, particularly in the sea. A prerequisite for such a study is that parasites have a long life and are acquired only in the population or area studied. Larval helminths fulfill these conditions and are therefore usually used. Examples for the successful use of parasites as biological markers are studies that demonstrated different populations of herring with different *Anisakis* infections in the Baltic Sea, different populations of Atlantic salmon from different tributaries of the Miramichi River system in Canada, and different populations of sockeye salmon in the North Pacific, one harboring the nematode *Dacnitis truttae* acquired in

Kamchatka and one harboring the larval cestode *Triaenophorus crassus* acquired in western Alaska.

The von Ihering Method

About 100 years ago, von Ihering first used parasites and ecto-commensals to clarify places of origin and dispersal of hosts and ancient land connections between land masses. One assumption of the method is that animals have acquired the greatest diversity in the area where they have been the longest. Mamaev and Margolis applied the method to Pacific salmon. On the basis of their finding that salmonids harbor many freshwater parasites, some of them with complex life cycles, but no marine endoparasites, they concluded that salmonids are of freshwater origin. Many similar studies have been carried out.

Economic and Hygienic Importance of Parasites

Human Parasites are Among the Most Important Disease Agents of Man

The web pages of The World Health Organization, Division of Tropical Diseases (CTD), and of the Centers for Disease Control (CDC) contain information about the current status of the important parasitic diseases, which is continually updated. Information about the most important parasites of humans is given in **Table 5** and **6**. Note that some of the most widespread species, such as *D. folliculorum*, a mite infecting the skin, and *To. gondii*, are not included because of lack of data and usually symptomless infections.

A number of parasite species, most of them protozoans, including the nematode *S. stercoralis*, have recently become more important because of AIDS. All these species multiply within the human host and may become fatal in immunodepressed patients. The protozoans involved are, among others, *Cryptosporidium* and *Giardia*, sometimes acquired in polluted drinking water, *Pneumocystis carinii*, *Microspora*, and *Entamoeba histolytica*.

Resistance has developed to drugs used against various parasite species and to insecticides used against various vectors.

Figure 10 Metazoan ecto- and endoparasites on the heads and gills of marine teleost fish at various latitudes. Reproduced from Figure 1 in Rohde K and Heap M (1998) Latitudinal differences in species and community richness. *International Journal for Parasitology* 28: 461–474.

Table 5 Human infections with the most important parasites worldwide

Parasitic infection	Number infected (million)
Intestinal roundworms	1400
Malaria	300
Bilharzia	200
Lymphatic filariasis	120
Amebiasis	40
Food-borne trematodes	40
Chagas disease	16–18
Leishmaniasis	12
Sleeping sickness	0.3
Guinea worm	0.1

Source: Reproduced from McGill: The World of Parasites (<http://martin.parasitology.mcgill.ca>).

Hence, the epidemiological situation is becoming worse. Malaria is becoming more prevalent in many countries, not only due to insufficient financial and human resources for control but also because of human-induced climatic and environmental changes, migration, and war. Likewise, the prevalence of intestinal parasites worldwide is increasing, partly due to increasing

Table 6 Infections of the most common parasites in some countries/regions

Region	Infection	Number infected
United States	Pinworms (<i>Enterobius vermicularis</i>)	50 million
	<i>Strongyloides stercoralis</i>	<1 million
South America	Bilharzia	45 million
	Chagas disease	16–18 million
	<i>Strongyloides stercoralis</i>	ca. 7.4 million
Africa	<i>Ascaris lumbricoides</i>	> 200 million
	Bilharzia	100 million (mortality, 0.01 million)
	Malaria	23 million (mortality, 2.6 million)
China	<i>Ascaris lumbricoides</i>	ca. 100 million
	<i>Opisthorchis sinensis</i>	5 million
Middle East	<i>Ascaris lumbricoides</i>	100 million
	Hookworms	60 million
	Bilharzia	50 million

Note: *Demodex folliculorum* and *Toxoplasma* not included.

Source: Reproduced from McGill: The World of Parasites (<http://martin.parasitology.mcgill.ca>).

urbanization. In contrast, the global prevalence of guinea worm (*Dracunculus medinensis*) has decreased from about 10 million 10 years ago to about 150,000 (most of them in the Sudan), as a result of a campaign to eradicate the infection. Almost certainly, malaria and several other important parasite diseases would spread into areas presently not affected if global warming as a result of the greenhouse effect should occur.

Parasites of Livestock also Have Very Great Economic Importance

For example, nagana, a disease of many domestic animals caused by *Trypanosoma brucei brucei* and transmitted by tsetse flies in Africa, has made large areas of sub-Saharan Africa unsuitable for livestock production, and nematodes of sheep and cattle cause large economic losses in many countries. *Ostertagia ostertagi*, one of the nematodes infecting cattle, is estimated to cause an annual loss of \$600 million to the cattle industry in the USA alone. The situation is not improving because of drench resistance of

nematodes. Thus, in Australia, about 90% of sheep farms have worms resistant to one or more drench classes.

Parasites Have Repeatedly Caused Large Economic Losses in the Fisheries Industries

In particular, aquaculture is affected. On the East Coast of North America, for example, several protozoan parasites have repeatedly decimated oyster culture in several areas. The haplosporidian *Haplosporidium nelsoni* caused a decline in oyster production in the New Jersey waters of the Delaware Bay from about 5–8 million pounds between 1950 and 1955 to 167,000 pounds in 1960, which has never fully recovered (Figure 11).

Many Parasites, Particularly Nematodes, Are Among the Most Important Pests of Plants

For example, wheat is attacked by the nematode *Anguina tritici*, potatoes are attacked by the potato cyst nematode

Figure 11 Oyster production in Delaware Bay, East Coast of the USA. *Note:* Collapse of oyster production in the late 1950s due to the haplosporidian *Haplosporidium nelsoni*. Modified after Sindermann, with permission from Rohde K (1993) *Ecology of Marine Parasites*, 2nd edn. Oxford: CAB International.

Globodera rostochiensis, and rape, rice, etc., all have their specific nematodes that lead to large economic losses. The estimated annual loss to crop production due to nematodes in the USA is \$8 billion (12%), and it is \$78 billion globally (http://ianrwww.unl.edu/son/nn_nema.htm).

Parasitic Angiosperms Attack Many Crops

At least 11 species of witchweed, *Striga* spp., attack crops, including all the important tropical cereals; control is difficult because of the high production of seeds and longevity of seeds up to 20 years in the soil. Dwarf mistletoes almost always cause deformities of trees, leading to a substantial reduction in the yield and quality of timber. The mistletoe *Viscum album* reduced the yield of a particular apple variety in the UK by 7–54% (Press and Graves, 1995).

Parasites, Including Nematodes, Are Increasingly being Used to Control Insect Pests

Neoaplectana carpocapsae is bred in the laboratory and sprayed on rape to combat insects attacking it, and *Howardula* sp. effectively kills the dried-fruit beetle *Carpophilus mutulatis*. *Heterorhabditis bacteriophora* kills insects by carrying bacteria into them.

Glossary

Affiliative behavior Behavior that is supportive and brings individuals together.

Agonistic behavior Behavior that is aggressive, threatening, combative, and submissive.

Altruism Behavior that enhances the recipient's reproduction while reducing the actor's.

Cooperative breeding Social system in which more than two individuals care for young.

Musth Annual reproductive period in male elephants characterized by extreme aggressiveness and secretions from temporal glands.

Polyandry Mating system in which a female mates with more than one male.

Polygyny Mating system in which a male mates with more than one female.

Protandry Breeding system in which individuals change sex from male to female.

Protogyny Breeding system in which individuals change sex from female to male.

Introduction

No animals are completely asocial. All must come together at some point to breed. Few, however, are highly social coming together and interacting repeatedly. For those that do interact frequently, social interactions – both affiliative and agonistic – occur sometimes with relatives, sometimes with strangers, sometimes with members of the same sex, sometimes with members of the opposite sex; and sometimes with members of the same generation while at other times with members of other generations. The interactions themselves can be aggressive, cooperative, or even altruistic and can develop into strong relationships among particular individuals. Depending on the nature of these relationships and with whom they form, a variety of social systems can develop. Some may be made up mostly of kin or mostly of nonkin, some may be based on territorial separation or on the aggregation of competitors, some will exhibit monogamous as opposed to polygamous relationships between the sexes, and some will rely on the cooperation and help of nonmates in the rearing of offspring. This seemingly bewildering range of social diversity is shaped ultimately by ecological circumstances and patterns of demography. But the very nature of a population's social structure itself will in turn affect the population's demography and its place in the biological community. It is these dual connections between social activities and the environment and the resulting feedbacks that mandates understanding both the causes and consequences of animal sociality so that effective and efficient management or conservation policies can be developed for protecting endangered species and for preserving biodiversity and ecosystem integrity.

From Social Behavior to Social Organization: Patterns and Mechanisms of Formation

Social animals form groups. While some are temporary, others are more permanent. Given that animals in groups incur

automatic costs of increased disease and parasite transmission as well as intensified competition, groups will only form when there are sufficiently large benefits to offset these costs (Alexander, 1974). Benefits largely come in three forms. First, animals can develop forms of social behavior specific to stable groups that compensate them for the costs of group living. One such example is forming mutual grooming partnerships as do olive baboons (*Papio anubis*) to lower disease and parasite transmission. Second, by forming groups animals can enhance foraging by being better able to find, acquire, or defend food. Examples include colonial cliff swallows (*Hirundo pyrrhonota*) that transfer information about the locations of rich but ephemeral feeding sites or troops of monkeys that drive smaller troops away from feeding trees. And third, animals in groups can reduce their risk of being preyed on by either increasing the likelihood of detecting predators, diluting their personal risks, or by decreasing the likelihood that predators can make a kill; confusion and cooperative defense are mechanisms that provide such antipredator benefits. Examples include the scattering of fish in schools, or the gathering of young inside a ring of adult musk oxen (*Ovibos moschatus*) facing outward toward approaching predators with upturned horns.

Depending on the nature of the social relationships that develop among individuals, groups take on particular organizational forms (Emlen and Oring, 1977; Rubenstein, 1986). As Figure 1 illustrates, these relationships are shaped by the features of an individual's ecological and social environment. Particular distributions of food or water (bottom-up factors) and predators (top-down factors), in conjunction with the physiological demands of individuals differing in body sizes or reproductive states, will determine the frequency and magnitude of competitive and cooperative interactions that occur. The outcome of these repeated social interactions will shape overall time budgets and activity patterns. Because females maximize their reproductive success relative to other females by their ability to raise offspring to the age of independence, females are forced to efficiently solve the three ecological problems: finding

Figure 1 Model of ecological and physiological pressures influencing both intra- and intersexual relationships and showing how they shape social systems. Arrows depict social relationships. What type of society develops depends on details and perceptions of environmental conditions and interactions between males and females.

food or water; avoiding predators; or finding safe sites for young (Figure 1). The particular associations and distributions that develop will depend on the particular ecological and physiological circumstances that females experience. These associations and distributions in turn will shape male associations and distributions, because male fitness is mostly determined by their ability to acquire mating access to disproportionate numbers of females. Especially for mammals, the mating system that develops becomes the core of a species' social system.

Ecological Challenges and Phenotypic Constraints

Resource distribution in time and space shapes animal social systems (Emlen and Oring, 1977). In environments in which resources are abundant but evenly distributed, competition is low enough to permit females to aggregate. If sufficiently large foraging or antipredator benefits can be derived by females that aggregate, and the groups that form are not too large, then these groups can be defended by single males and so-called "harem defense polygyny" results. If resources, however, are more patchily distributed so that competition among females intensifies periodically, then female group sizes will vary and female associations become more transitory. Rather than defending unstable groups of females, males instead attempt to defend resource patches sought by females. Typically, in these systems of "resource defense polygyny" the most able males defend the best patches and thus gain access to the largest

number of females for the longest periods of time. If resources are not only patchily distributed, but also the patches are large, widely separated, and fluctuate seasonally in abundance, then competition among females becomes so low that the formation of large groups is even more likely, provided that females can range widely and follow the shifting locations of peaks in food abundance. Males will thus be forced either to follow these large groups competing for, and then tending, one reproductive female at a time ("wandering") or to position themselves at the intersection of female migratory routes and wait for females to visit them ("lekking"). In the first case, intense male-male competition generates a mating system based on "male dominance polygyny," and in the latter case females are afforded the exquisite opportunity to simultaneously compare many males before choosing with which one to mate! Whenever resources are sparsely but somewhat evenly distributed, high levels of competition prevent females from forming groups. As a result, individual females defend territories thus ensuring a regular supply of a renewing resource. Since solitary individuals searching for members of the opposite sex will face increased predation risk, pairs often share territories and monogamy results.

This model accounts for the diversity of mating systems for many different groups of animals including insects, fish, reptiles, rodents, and many varieties of birds, ungulates, carnivores, marine mammals, and primates. One of the best illustrations showing how environmental forces interact with physiological constraints to shape a species' social system emerges from Peter Jarman's classic study of African antelopes (Jarman, 1974). By showing how body size affected the ways in which different species perceived, and then responded to, the distribution and abundance of forage and predators of grasslands, Jarman showed why particular social systems increased survival and reproductive prospects for particular species. He argued that the smallest bodied species, such as dik-dik (*Madoqua kirkii*), duikers (*Cephalophus* spp., *Sylvicapra* spp.), suni (*Neotragus moschatus*), and klipspringers (*Oreotragus oreotragus*) require limited amounts of high-quality vegetation. But given their small size, such food items often appear as if they are widely scattered. Faced with high levels of competition and intensified risks of predation, territoriality and monogamy appear to be the best strategies. Pairs generally live in wooded or shrub-rich areas where moisture enables vegetation to grow and renew itself well into the dry season. By signaling territorial ownership via scent rather than by means of sound or visual display these small-bodied species reduce the chances that any of a large number of carnivores will prey on them. As species increase in body size, both physiologically determined dietary needs and the way acceptable forage becomes distributed on the landscape changes. Since hiding or "crypsis" becomes an untenable antipredator strategy for larger and more widely ranging species, forming groups becomes the best strategy for larger species to lower predation risk. Fortunately, with larger size also comes an ability to subsist on more abundant, lower quality vegetation. When food is patchily distributed, as it is for impala (*Aepyceros melampus*), reedbuck (*Redunca* spp.), and some gazelles (*Gazella* spp.), males defend the best patches that females prefer. When the vegetation is more evenly distributed, which often results simply from the fact that larger

species such as eland (*Taurotragus oryx*) and Cape buffalo (*Synceros caffer*) can utilize even the lowest quality items, larger groups form. Because the biggest species view large continuous swards of a landscape as acceptable, competition is virtually eliminated and many males associate with many females. With such high levels of male–male competition, defense of a small subgroup of females becomes impossible and dominance defense systems develop.

The same sorts of connections between changing ecological circumstances shape the types of sociality exhibited in other taxa. A brief survey of mammals illustrates some of the more general patterns. For the equids the close association between food and water enable horse (*Equus caballus*) and plains zebra (*Equus burchelli*) females of different reproductive states to associate permanently (Rubenstein, 1986, 1994, 2010). Thus, males are able to defend such groups and so-called harems form. When these two resources are widely dispersed, as for Grevy's zebra (*Equus grevyi*) and the Asiatic wild ass (*Equus hemionous*), females of different states are precluded by metabolic constraints from foraging together. As a result, males compete for territories along traveling routes that take females from feeding areas to watering points.

In felids, females remain separated when food is scarce and the habitats are densely wooded because in such circumstances individual prey can be caught and consumed before competitors can intervene. In more open habitats and where both prey and competitors are large and much more numerous, coalitions of females form to help hold on to kills until they are completely devoured. If these female coalitions are themselves large, then there is pressure for males to aggregate to control reproductive access to females. Thus, the only highly social felid is the savanna-living lion (*Panthera leo*), yet even in this plentiful landscape the leopard (*Panthera pardus*) remains solitary because it can safely catch its large prey in trees (Packer, 1986).

For canids monogamy is the rule. But variations do occur with small-bodied foxes (*Vulpes* spp.) sometimes exhibiting polygyny and large-bodied hunting dogs (*Lycaon pictus*) and timber wolves (*Canis lupus*) developing polyandry (Moehlman, 1986). Typically canids need help from nonbreeding foragers to help nourish lactating mothers. For the midsized jackals, such as the silverback jackal (*Canis mesomelas*), the helpers are young from previous litters that cannot themselves find successful breeding locations. For the smallest species, however, prepartum investment in young is relatively small for a female and thus her mate provides all the help that is needed. In years when prey resources are very high, competition between mothers and their soon-to-be-fecund daughters is low and their daughters are not forced to disperse. As a result they provide neighboring males with additional mating opportunities. For the largest bodied species, however, female prepartum investment is very high and they need all the help they can get. To enlist the support of other adult males that must hunt cooperatively to capture large prey, a dominant female not only kills the offspring of other females in the group, but also she mates with their mates so that these males behave as if they are the sires of the dominant female's young. Hence, depending on size-determined metabolic investments and needs, social systems of canids can vary from polygyny to polyandry and sometimes use the services of juvenile or adult nonbreeders to help rear offspring.

Monogamy is also the rule in birds, with more than 90% of all species exhibiting social monogamy. Unlike in mammals, where mothers are typically able to take care of offspring on their own, bi-parental care is essential for producing young in most birds. However, this does not mean all pairs are faithful. Although more than 90% of birds are socially monogamous, an almost equal percentage of these seemingly faithful species are not actually sexually monogamous. Although rarer, other forms of mating systems also occur in birds. When resources are clumped, males defend those that are essential to females. For example, in many species of hummingbirds, males defend territories when flowers that females need are sufficiently clumped. Lekking is particularly common in birds compared to mammals. Some of the most recognizable avian species, like the ornamented birds-of-paradise, the bowerbirds and their decorated bower structures, and the dancing manakins lek. In these species, males cannot defend resources or females, and so they aggregate in areas where females are likely to compete against each other for female attention.

Ecology not only shapes animal mating systems, but also in some cases, the social systems themselves. Many species of vertebrates live in complex societies where individuals delay dispersal and independent breeding opportunities to help other group members raise their young. In these "cooperatively breeding groups," dispersal decisions are typically influenced by ecological factors. Limited resources, such as territories, nest sites, and even mates, prevent young individuals from dispersing to breed on their own. Although the spatial distribution of resources on the landscape can influence dispersal and helping decisions, temporal variation in resource abundance may also affect cooperative breeding behavior. In birds, cooperatively breeding species tend to be found more often in unpredictable environments where rainfall and resources vary erratically from year-to-year. Having helpers-at-the-nest may allow cooperatively breeding species to buffer these uncertain times better than those species without these nonbreeding auxiliaries (Rubenstein and Lovette, 2007, Jetz and Rubenstein, 2010).

Kinship and Demography

Although the abundance and distribution of key ecological resources are important in determining the particular pattern of cooperation and sociality exhibited by a population, other factors such as kinship and demography also play significant roles. Since W. D. Hamilton formulated the concepts of "inclusive fitness" and "kin selection," the magnitude of the costs and benefits associated with particular social behaviors that ultimately determine which strategy is the best, had to be adjusted by degree of relatedness between social partners. Altruistic or cooperative behavior between relatives should be favored whenever $\text{Benefits} > \text{Costs} \times r$ where r is the degree of relatedness. For both parents and offspring and among full siblings, $r = \frac{1}{2}$ for grandparents and grand offspring and among half-siblings, $r = \frac{1}{4}$, and among first cousins, $r = \frac{1}{8}$. Hence, the stronger the degree of relatedness among relatives, the more likely altruists are to enhance the reproductive opportunities of kin while incurring costs associated with diminished personal reproduction. Thus, in the examples presented here, it is not surprising to find that the coalitions

that form among lionesses when protecting kills and among male lions when protecting mating opportunities with females are formed most often among full siblings; nor is it surprising that the helper jackals recruit to rear additional offspring are themselves the full siblings of the offspring being raised. In general, strong kinship lowers the threshold for the appearance of altruistic and cooperative behavior and may substantially affect the costs of living in groups, particularly in cooperatively breeding species.

Nowhere is this more apparent than in elephant societies (Archie *et al.*, 2006) (Archie *et al.*, 2006). As is the case in many mammals, elephants live in fission–fusion societies in which individuals, or the subgroups they inhabit, separate and merge from time to time. In African elephants (*Loxodonta africana*), up to 20 individuals and their young live in core family groups in which daughters remain after reaching sexual maturity, while males leave. Depending on ecological conditions, core groups can separate into smaller units or merge with other core groups to form bond groups. Extensive genotyping of individuals using molecular DNA markers show that not only do family groups typically consist of close genetic relatives, but also that bond groups are most likely to form when the oldest females of the core groups were genetic relatives.

But as many of these cases illustrate, high population density and the intensified competition elephants engender for finding suitable territories with sufficient food and habitable burrows are the factors ultimately responsible for favoring the establishment of coalitions of relatives or the recruitment of helpers in cooperatively breeding societies. Thus, demographic factors, such as population density as well as sex ratio and age structure that result from differences in phenotype-specific vital rates also shape patterns of social organization. And since these features of populations are often altered by human activities, understanding how they shape, and are shaped by, patterns of sociality is essential if conservation assessment and planning are to be effective.

Hypothetically, if mortality, for example, were age specific and higher for prereproductive females than males, then high breeding sex ratios (males/females) would result and mating relationships would generally become more polygynous. If the sex-specific patterns of mortality were reversed, however, then polyandry would become more common. Since some of these mortality concerns were responsible for the variation in canid social structure described earlier (*see Ecological Challenges and Phenotypic Constraints*), these mortality schedules can have important consequences. Similarly, if mortality rates were size specific and happened to be greater for larger males rather than smaller ones, then discrete size polymorphisms could arise in populations. This appears to be the case regarding the maintenance of so-called alternative male mating strategies. Often the typical strategy adopted by older and larger males of defending harems or resources yields the most reproductive gains but it often incurs the highest costs as well. Because displaying, fighting, attracting the attention of predators, and delaying reproduction while growing are all costly activities, males adopting not only less successful but also less costly tactics can also flourish (Rubenstein, 1980).

Maintenance of such alternative mating patterns is common among many species of insects, fish, amphibians, birds, and mammals. For example, in bluegill sunfish (*Lepomis macrochirus*)

males typically defend nest sites where they display, attract females with which to mate, and then fertilize and guard the eggs they lay. Since only the largest males have the ability to defend such nest sites, they must delay breeding in this fashion often for more than 7 years. As a result, smaller and younger males have evolved various cuckolding strategies that may in fact be equally successful evolutionarily. In one, the so-called sneak begins breeding at 2 years of age. Although very small, such sneaks are virtually all testes and because of their inconspicuousness can dive from the surface just as a mating pair release sperm and eggs. By exuding large volumes of sperm, some make it to the eggs and fertilize a few. In the other, males delay breeding for as long as do females. By being the same size and color as females, these males join the mating pair and apparently fool the displaying male into thinking that he is courting two females. Then as the original pair releases their gametes, he does too and thus fertilizes some of the females' eggs. For these two strategies to be equally successful alternatives, the costs and benefits of each must vary inversely with frequency. Although they sometimes do, as in the case of the bluegill sunfish, in other species they do not (Gross 1991; Brennan *et al.*, 2008).

A variant on this theme is associated with sex change. For many species, especially among the fishes, individuals begin life as one sex and end life as another. In bluehead wrasse (*Thalassoma bifasciatum*), for example, most individuals begin reproducing as females while residing with one male. If he disappears, then the largest female changes sex and becomes the harem-tending male (Warner *et al.*, 1975). Alternatively, in anemonefish (*Amphiprion* spp.), some individuals change from male to female. In either protandrous (male first) or protogynous (female first) species (Fricke and Fricke, 1977), the sex that is last is the one whose reproductive success is most influenced by body size, and this ultimately depends on the nature of the social system.

Clearly, a variety of environmental features influence the patterns of sociality that populations of animals develop. In many cases these patterns are flexible and species can vary in the system of social organization they exhibit depending on environmental conditions. Thus, although female burros and asses typically live in transitory groups whose membership changes, when populations move from arid to mesic areas, social relationships can change. As was found on an island off the coast of Georgia, with food and water both more abundant and less separated, females with differing needs can and do coalesce into permanent groups. Males, which in arid areas are forced to establish territories along routes to and from water, respond by defending these groups much like males of horses, their close kin, and harem-like societies emerge. In some species of birds where pair-bonds are the norm, cooperative breeding groups form via the retention of offspring during hard times. In these occasional, or "facultative" cooperative breeders, flexible social behavior is an important part of their social lives.

Egalitarianism and Despotism

In some societies, rewards are relatively evenly distributed among members, whereas in others they are not. When animals compete for critical resources, differences in fighting

ability often lead to skewed payoffs, with dominant individuals securing a disproportionate number of rewards, which are typically related to reproduction (Hager and Jones, 2009). The degree to which dominants can control the actions of subordinates varies. If it is incomplete and the rewards to subordinates low, then subordinates will be induced to leave and dominants will suffer. Thus, dominants may be constrained to concede some resources to subordinates. For males, skew is often related to mating opportunities and recent models suggest that when control by dominants is incomplete, the degree of skew will depend mostly on ecological factors and fighting ability (Reeves and Shen, 2006). In meerkats, for example, reproductive success of subordinate group members increases with increases in body condition and years with high rainfall (Clutton-Brock *et al.*, 2001). Thus, for highly social and cooperatively breeding species, the genetic diversity of populations and the diversity of behavioral strategies they exhibit are likely to change with changes in climate and environmental features.

The existence of dominance hierarchies is a fact of life for most social species, and as noted above, play an important role in structuring societies, skewing payoffs, and when those payoffs are tied to reproduction, affecting the long-term evolutionary sustainability of species. But the degree to which dominance influences these outcomes depends on the costs of achieving and maintaining dominance ranks, since high costs often shorten life span and reproductive potential. Conventional wisdom based on many studies posits that dominants only experience high levels of stress in unstable societies. But recent work on baboons shows that even in stable societies life at the top can be stressful. While stress levels in baboons generally decrease with rank, alpha males exhibit cortisol levels equal to those of the most subordinate members of the group and are much higher than those of males immediately below the top male (Gesquiere *et al.*, 2011). Given that life at the top is likely to be costly for social species in both stable and unstable societies, it is likely that as deteriorating environmental conditions exacerbate competition for resources and mates, the longevity of alpha males will be decreased, thus altering the genetic diversity of populations and perhaps their demographic potential as well.

Organization and Networks

Social organizations are often characterized by general characteristics such as the number and types of mating pairs or the stability of relationships. But such qualitative characterizations can often be misleading and hide subtle differences in the function or causation of societies. As a result, tools from network theory are being used to quantify the overall structure of societies and the degree of “centrality” and extent of connectedness (termed “betweenness”) that individuals display within societies. The use of such quantitative measures is particularly important for fission–fusion societies where individuals often form many different types of relationships. In equids, for example, both Grevy’s zebras and Asiatic wild asses live in societies in which males generally live apart from each other and defend territories while females move among territories singly or in groups that regularly change membership.

When networks of proximity based on who has been associating with whom are constructed, the graphs they produce are very different (Figure 2) (Sundaresan *et al.*, 2007). Inspection shows that just about every wild ass is connected to every other wild ass and that individuals are organized into one large community. In Grevy’s zebra, however, more communities (called “connected components”) exist, even though within each community every individual is connected to every other individual. In general, individual Grevy’s zebras show higher levels of centrality than onagers because the number of close associates (termed “degree”) is greater in Grevy’s zebras than in wild asses. In addition, “cliquishness” of Grevy’s is greater than wild asses because the close associates of particular Grevy’s zebras are more likely to be close associates themselves than in the wild asses.

By computing these and other metrics, social network analysis provides a means of quantifying a variety of different features of society. And by doing so, social network analysis can help assess how social structure can cope with, or perhaps evolve in response to, environmental factors. For example, the metrics described in the previous paragraph reveal that Grevy’s zebra society is characterized by more modularity than that of wild asses and that this difference corresponds to a difference in the uncertainty of resource availability and levels of predation that each species experiences. Whereas wild asses live in environments in which humans have extirpated predators and have provided many predictable watering points, Grevy’s zebras face mobile predators and large fluctuations in rainfall due to periodic and unpredictable periods of drought. Network modularity appears to help prevent the loss of important information for coping with environmental fluctuations.

From Social Organization to Ecological Impacts

Despite the fact that some species exhibit social flexibility and that there exists significant “environmental determinism” in the development of patterns of sociality, knowledge is only now emerging about how changes in social systems impact important vital rates, alter interspecific competitive abilities, and shape a population’s growth rate and genetic structure. Never before have the social systems of so many species been forced to respond to human activities, most of which lead to reductions in population size, through overharvesting, fragmentation of landscapes or habitats, and changes in the earth’s climate. How are we able to predict which species will respond and how will a species’ response impact its long-term growth and the health of the ecosystem in which it resides? When we intervene will we do so with a sufficient understanding of what the consequences of changing social behavior and social systems are likely to be? For example, will we know when a species switches from a monogamous to a polygynous social system and whether its growth rate or genetic diversity will increase or decrease? Will we know whether it will be more or less able to withstand selective harvesting or habitat fragmentation? Such consequences of differing patterns of sociality must be understood before endangered species or their habitats can be protected. At least for free-ranging horses attempts to limit population growth using immunocontraception has led to a cascade of unintended

Figure 2 Network graphs of the fission–fusion societies of Grevy's zebras and Asiatic Wild asses. Both societies have one individual who is isolated from everyone. In general, Grevy's zebras exhibit more modularity than wild asses where virtually everyone individual is connected to every other individual.

consequences that have altered group stability and mating patterns (Madosky *et al.*, 2010) as well as the length of the breeding season and long-term male–females social and reproductive relationships (Nuñez *et al.*, 2010).

Consequences of Social Change

Many examples are now appearing of human induced changes in species' social systems. One population of feral horses inhabiting a barrier island off the east coast of USA has been impacted twice by human activities and both the times major changes to social behavior and social organization resulted in large-scale changes in the population's vital rates. The first instance occurred when dredging of surrounding ship channels altered currents and sediment deposition around the island. Before the emergence of hundreds of hectares of a new continuous sward of grassland, the island's horses exhibited two types of social organization. Where the vegetation was abundant and evenly distributed, females formed permanent membership groups and associated with a single male. Such harem groups were stable and males protected their females from harassment by intruders and rarely herded their own females. Where the preferred high-quality vegetation was broken up into patches of variable size by extensive ridges of sand dunes, females were not able to aggregate into permanent membership groups. As a result, males wandered in search of reproductively receptive females and, when doing so, harassed females and limited their ability to forage. Not surprisingly, the body condition and reproductive success of the harassed females was much lower than that of females bonded to males. After the emergence of the new sward of grassland in the region where females lived in the fission–fusion type of society, females were able to aggregate and males were able to establish harems and the growth rate of the entire population increased markedly. Thus, when the abundance

and distribution of key ecological resources alter social systems so that they more closely resemble a species' typical system, vital rates and the overall health of the population improve.

When the perturbation moves a population away from its normal pattern, as happened during the feral horse population's second brush with human activity, vital rates decline. As the horse population approached its carrying capacity, population control measures were instituted. During the initial round of management actions, more than 85% of the harem stallions were removed from the island. The resulting social disruptions were massive; many females were separated from their males and young, inexperienced bachelor males took over. Extremely high levels of harassment led to low reproductive rates despite the fact that overall density had also been reduced and food supplies were expanding. As these two disruptions illustrate, human activities that alter existing patterns of social relationships dramatically alter reproductive rates.

Similar outcomes occurred when large-scale El Niño induced climatic changes resulted in major adjustments to time and activity budgets of Alaskan red foxes (*Canis aureus*) (Zabel and Taggart, 1989). Before the 1982–1984 El Niño, many of the foxes on an island in the Bering Sea bred polygynously and produced litters of sizes equivalent to, and often greater than, those of monogamous pairs. After the El Niño and the reproductive failure of the large seabirds, the foxes shifted their diet to smaller, less abundant, and harder to catch prey. Dietary shortages were common, fewer foxes bred and polygyny disappeared. Moreover, the litter sizes of these monogamous pairs were smaller as well. Clearly, changes in social behavior in response to altered environmental conditions enabled some individuals to make the best of a bad situation. Overall, however, the health of the population suffered.

Major changes in the breeding patterns of elephants (*Lo. africana*) could result if climate changes alter the

patterning of grasslands in East Africa. Ordinarily group sizes and compositions change seasonally in response to changing abundances of vegetation. After the rains, when grasses grow rapidly on the extensive upland plains, small family groups of elephants aggregate into large matrilineal assemblages. With the flush of new vegetation many come into estrus and become reproductively active. At this time only the most dominant bulls come into musth, a heightened sexual and aggressive state. By aggregating, females incite male-male competition thus ensuring that they mate only with the best females. During the dry season, however, after the grasses on the plains stop growing and have been consumed by elephants and other ungulates, the elephants retreat to the swamps where other grasses and browse remain. The patchy nature of the habitat, however, prevents large groups of females from remaining together and the huge herds fission into smaller family units. In addition, few females remain to be mated and the dominant bulls go out of musth. Subordinates become sexually active at this time, but reproductive opportunities are limited. Thus, under a normal environmental regime two evolutionary consequences result: most males do not mate, but those that do are the most fit; and because genetic effective population size is affected by the number of males relative to the number of females mating, the effective population size of elephants is much smaller than the census population size. If global warming increases the duration and intensity of dry seasons, then selection for the best males will be relaxed but the effective population size of the population will increase, provided that elephants can sustain their high metabolic levels and maintain their high fertility and survival rates. With global changes in climate appearing in many different habitats, other examples of social readjustments that either change a species' evolutionary potential or that act as demographic shock absorbers in the short run, but are unlikely to provide compensatory relief in the long run, are likely to become more common.

Consequences of Demographic Change

Many demographic changes leave their mark by altering critical aspects of social behavior or by disrupting the development of important social relationships. As the elephant example illustrates, changing environmental conditions can change operational sex ratios thus altering a population's ability to maintain genetic diversity. But by changing sex ratios in other ways, humans can put populations at risk by making it difficult for them to grow in size. In lions, for example, trophy hunting, if it removed pride defending males and nomads in proportion to their abundances, would not severely affect population growth and effective population sizes would be maintained at normal levels. But if such hunting focused on pride males, then increased turnover would foster increased infanticide by take over males. While such diversification of the gene pool might increase effective population sizes, it would certainly lower population growth rates because infant survival, which is already low, would plummet. Much clearly depends on whether or not the population is polygynous or monogamous and whether the perturbation will accentuate or reverse the pattern. Large-scale climate

changes could reverse and ameliorate the normal pattern as is likely to be the case in elephants, but selective hunting or poaching, as in the case of lions, could exacerbate an already critical situation.

Selective poaching could even make it difficult for populations to recover once the poaching has been eliminated. Since hunting elephants for ivory meant that poachers sought the individuals with the largest tusks first, male numbers were reduced to dangerously low levels before large tusked females and smaller males were hunted. Because females prefer to mate with older males, lowered sex ratios and distorted age structures could make it difficult for all females to mate. As a result, population growth rates could remain low for historically heavily poached populations.

Harvesting in fish might be accelerating already rapid population declines because of disruptions to normal social interactions. When harvesting is size selective and reduces the number of large females in a population, fecundity might be disproportionately reduced since ovary volume scales allometrically with linear body size dimensions; larger females have disproportionately larger ovaries and high fecundity. And as sex ratios increase, male harassment of the remaining females may further reduce recruitment and population growth rate. When such size selective harvesting removes more males than females, sex ratios are reduced and females may become less choosy and more aggressive when selecting mates. While such changes in the intensity of sexual selection might not alter population growth rates, they might alter the genetic diversity of the population. Yet if males provide the majority of parental care and large males are removed from the population as is often the case in sports fisheries, then recruitment will be markedly reduced as unguarded eggs are cannibalized. The implications of overzealous size-selective harvesting in sex-changing fish or in fish that exhibit alternative male mating behaviors appear to be equally severe. For species such as anemonefish in which the largest males change to females, removal of the largest females will force males to change sex at ever smaller sizes, thus producing fewer eggs. Population growth rates will be curtailed and the species will find itself at risk all because of overzealous aquarium traders.

Migratory Atlantic salmon (*Salmo salar*) provide perhaps the clearest example of where human activities are changing the balance of male mating strategies within a population and hence the patterns of sociality. Atlantic salmon typically are born in fresh water and develop for 1–2 years before smolting and heading to sea to grow and fatten by feasting on a rich supply of marine invertebrates. Once they attain a certain size, they become sexually mature and return to rivers. There they travel long distances upstream until they reach clear and cool breeding grounds. Some individuals, however, never head to the sea. Instead, they remain in their natal streams and mature sexually at young ages and at small sizes. Such individuals are called parr and they never go through the smolting process that adapts them to a marine lifestyle. Under pristine environmental conditions, the fraction of the population that becomes parr is small since the reproductive gains of such a strategy are low. When competing for mates with larger more aggressive males, parr fare poorly. What matings they obtain are derived by "sneaking" among a mating pair and releasing milt at just the right time. Such events are rare and the mixing of milt is poor

so such “sneak” matings result in few young being sired. But the survival prospects of parr are high since they do not incur the risks of going to sea and, moreover, they begin breeding at a very early age. Thus, over a lifetime, reproductive success is moderate. But as human fishing increases and the netting of the older larger salmon intensifies, the relative lifetime reproductive success of parr is improving. Since the costs of migrating to sea and back again have increased dramatically, the long life span of parr give them a relative advantage. And given that competition with the larger males for mates is also being reduced, the chances of parr securing matings are also improving. Thus, it is not surprising that the composition of the population is changing as parr increase markedly in abundance. The impact on the long-term stability of the population is unclear. But the long-term impact on the balancing of mating morphs and sexual relationships is.

Consequences of Inappropriate Interventions

When humans intervene and develop management and conservation plans they sometimes do so without accounting for important aspects of social behavior. As a result some disastrous consequences have ensued.

Ignorance about the mating system of sperm whales (*Physeter macrocephalus*) has led to the implementation of harvesting plans that have almost led to their extinction. By using data from previous harvests in which the counts of males were much fewer than those of females, sperm whales were thought to exhibit a harem breeding system. Such a conclusion could only have been derived by assuming that sperm whales lived in permanent, closed membership groups. By making this assumption, the International Whaling Commission concluded that most males sighted would be superfluous thus disproportionate hunting of males would not limit the growth rate of the population; most of the males caught would not be necessary for fertilizing females.

Unfortunately, the social relationships of sperm whales are very different from those assumed. Females are the core of the society and do appear to live in permanent membership groups. But these groups often merge when diving for fish and divide labor between fishing and tending the young that cannot dive deeply. Males are forced to leave their natal group when reaching sexual maturity, but they cannot accompany the breeding associations to the tropics. Instead they remain at the higher latitudes foraging in the cooler more productive waters. Thus, when males are hunted on the breeding grounds it is breeders and prereproductives that are taken. With breeding males severely reduced in abundance and the younger, subadult upstarts located thousands of kilometers away, many females are going unmated. As a result, the population is failing to recover and it will be years before the next generation of males is ready to start the population, already handicapped by such a low recruitment potential, on the road to recovery. Knowledge about sperm whale social relationships could have prevented the mistaken over-harvesting of mature males.

Another species in which ignorance about important features of social behavior is problematic is the black rhinoceros (*Diceros bicornis*). During the past 25 years, numbers have

declined from 65,000 to fewer than 5000 in 2011 because demand for their horns is so great. In an attempt at making rhinos less desirable, some nations have implemented a strategy of dehorning. Other nations have opted to translocate rhinos to extremely well-protected areas. Unfortunately, horns, and thus the value of rhinos, regrow quickly. But what is more troubling about the dehorning treatment is that it appears to disrupt effective maternal antipredator behavior. Although dehorned rhinos were no more likely to flee from predators than intact rhinos, the disproportionate disappearance of offspring being reared by dehorned mothers as opposed to intact mothers in areas with large numbers of lions and spotted hyenas suggests that horns play a vital parental and protective function. Dehorning, although initially thought of a cure for the disappearance of adults via poaching, became a contributing factor to the disappearance of young via predation. Although dehorning might enhance adult survival in the short run, it would limit a population's growth potential in the long run.

A third example where ignorance hindered, but did not harm, a conservation program involved the reintroduction of Asiatic wild asses (*E. hemionus*) to habitats within its historical range. A goal of the Israeli government is to repopulate Judea and Samaria with biblical animals. Since the Palestinian race of the wild ass was extirpated by the Ottoman Turks at the beginning of the twentieth century, the onager was a prime candidate for translocation. The first reintroduction took place in 1982 with subsequent additions throughout the 1980s and increased the number of breeding females to 14. By the mid-1990s, however, the population had hardly grown and the number of breeding females totaled 16. What was not known at the time was that breeding success is bolstered by being reared in the wild and that onagers could facultatively adjust the sex ratio of the offspring they produced. In the Negev Desert, free-ranging onagers gave birth disproportionately to sons.

Trivers and Willard (1973) were the first to suggest that differences in the ability to invest in the successful rearing of offspring should lead to individual differences in the primary sex ratios of offspring. They argued that females with sufficient resources should invest in offspring of the sex with the higher variance in reproductive success. By producing well-endowed offspring of this sex, mothers would increase the number of grand offspring they were likely to have. In polygynous species like the onager, males are usually the sex with the greatest variance. Since onager females compete more on the basis of resource exploitation, or utilization efficiency, rather than via direct conflicts settled by social status, sex biases in offspring production were not expected. However, because age and experience affect utilization efficiency, differences in bodily condition and ability to invest in offspring were expected to exist among females in this onager population. Thus, it was heartening to find that middle-aged females – those in the best physical condition – gave birth to more sons than daughters. Conversely, those breeding for the first or second time gave birth to daughters as did older females nearing the end of their reproductive lives. The strategy the Israelis employed of translocating middle-aged females to the desert was sensible in economic terms since high risks were attached to releasing very young females and low future expectations were

associated with releasing older females. But had the Israelis released old females with yearling daughters they would have quickly accelerated the growth of the population. At the time, an understanding of how environments shape patterns of onager social behavior and the impacts that these behaviors would have on population dynamics was unknown.

The Kakapo (*Strigops habroptila*), a critically endangered ground-dwelling parrot native to New Zealand, represents another conservation story where sex-ratio manipulation may be critical to saving the species. Males, the largest parrot species in the world, are not only larger than females and better able to escape predators, but also females are particularly at risk of predation when incubating nests. In 1982, all remaining birds in the wild were brought into captivity. Of the 62 remaining birds in 2001, less than 30% were female and only six female fledglings had been produced since 1982. Owing to the supplemental feeding in captivity, most females were producing sons. After deciding not to boost female condition through supplemental feeding, the offspring ratio evened to approximately 50:50 and more daughters have since been produced.

Most animals exhibit some form of social behavior. Much of this behavior is intimately tied to the environment in which the organisms live. By understanding the relationships between environments and social behavior and between social organization and population processes, we should be in a better position to understand the problems endangered species are likely to face and what interventions to protect them are likely to be effective. In a time when global warming is a reality and human modification of the landscape is occurring at alarming rates, gaining a better understanding and appreciation for animal social behavior will help in preserving species and ecosystems across the planet.

Species Assemblages, Macroecology, and Global Change

Brian J McGill, University of Maine, ME, USA

Glossary

β diversity How two assemblages at different points in space differ (or equivalently how the composition of an assemblage changes as one moves across space).

Assemblage A group of organisms found within some specified geographic area at one point in time that are evolutionarily related and that include many species, typically spanning across a taxonomic Family, Order, or Class.

Frequency distribution A histogram or description of the distribution of values. The frequency distribution not only contains information about the mean and the variance, but also higher moments. The normal (or Gaussian distribution) is the best known frequency distribution. But many aspects of assemblages show a lognormal distribution. Empirical data may show a

frequency distribution that is not a good match to any known theoretical distribution.

Scale The order of magnitude, length, area or time period relevant to the data being collected and processes being studied. Thus a small scale might be data collected within one square meter, while a large scale might be data collected spanning 100 square kilometers.

Trait Any property (usually quantitative) of an individual that can be measured. The distribution of traits in an assemblage then gives a representation of the assemblage with respect to that property. Some properties (e.g., abundance or range size) can only be measured at the species level, which technically makes them not a trait, although the author will refer to “species traits” as a shorthand.

Species Assemblage Basics

Definition

Ecologists have long been fascinated by studying systems with more than one species. Thus, community ecology is one of the older subfields in ecology. But ecologists have been surprisingly vague about what exactly is the proper unit of study when more than one species is involved. Terms such as community, guild, assemblage, etc. have all been invoked. To an insider, there are nuances associated with different words. Community emphasizes a group with strong interactions between the species. Guild implies a group that shares and competes for a common resource. Assemblage is usually recognized as a relatively looser group. The rise of macroecology (Brown and Maurer, 1987; Brown, 1995) has chosen to focus on the assemblage as the unit of study, while still not providing a precise definition. In attempting to bring clarity to this terminological thicket, Fauth *et al.* (1996) identify an assemblage as a group of organisms that share a common geographical location and a common phylogenetic history. This accords reasonably well with the sense used in macroecology. Brown (Brown, 1995) notes “Most (macroecological) hypotheses and analyses require that the organisms being considered be not precisely identical but at least comparable, in the sense that they are subject to similar evolutionary and/or functional constraints”. Thus, for the purposes of this entry, an assemblage is defined as “a group of organisms found within some specified geographic area at one point in time that are evolutionarily related and that includes many species, typically spanning across a taxonomic Family, Order, or Class”. Thus, the birds of Yosemite national park are an assemblage, as are the sphingid moths of North America.

Processes Acting on an Assemblage

An assemblage, like any other entity studied in ecology, is of interest because it is presumed that there is a common set of forces or processes that affects all examples of assemblages, allowing for the development of a general theory about which forces have what effects under what conditions. Broadly there are five types of processes that are presumed to drive most of the variation and pattern that we see in assemblages:

- Biotic filtering – species interactions such as competition, disease, or predation that limit which species can be part of an assemblage.
- Abiotic filtering – environmental constraints such as frost or drought that limit which species can be part of an assemblage.
- Evolution – the processes of speciation and global extinction that control which species can potentially occur in an assemblage.
- Dispersal limitation – when some species that could exist within an assemblage do not simply because they have not sent propagules to the geographic area of the assemblage. Dispersal limitation is often perceived largely as random and thus as the main way in which stochasticity is incorporated into assemblages.
- Sampling – when small areas are studied, only a few individuals can fit into the area. Because the few individuals cannot possibly span the diversity in the larger region, random sampling determines which species, traits, etc. are represented in small areas.

Thus, the study of assemblages is about determining the effects and relative importance of these five forces.

The Role of Scale

One of the most important determinants of which processes are most influential on an assemblage is the spatial scale. The definition given above of an assemblage was fairly specific about what taxonomic extent applies (Family through Class) but extremely vague about spatial scale. Under the definition given, an assemblage could be anything from the birds of Frank Preston's back yard to the globe, and indeed assemblages of birds have been studied at both extremes (Preston, 1960) and nearly every scale in between. If the one word "assemblage" is going to be used to cover such a range of scales, it is important to recognize that the relevant processes may change with scale. The current working assumption (although it is still a hypothesis needing more testing) is that biotic filtering and random dispersal limitation are most important at very small scales. As the scales get large enough to cover varying climates, abiotic filtering becomes important. And at the largest scales, speciation and extinction become important as well as the fact that dispersal events are now exceedingly rare leading to preemption effects (the first species to successfully migrate influences the long-term trajectory of evolution).

Describing an Assemblage

The simplest description of an assemblage is a list of the species present. A much more useful description gives not only the list of species but also the abundance of each species (Table 1). Such descriptions, however, are rather cumbersome and assume the reader is well acquainted with the biology of the species in the list. The next five sections present five different ways of describing assemblages. The first two ways are short in comparison to a list (Table 1) and represent ways to summarize an assemblage. One focuses on means and other univariate descriptions of assemblages, while the second summarization captures the broader distribution; but both methods lose the detailed list of species identities. The third approach involves looking how different attributes of an assemblage are related to each other. The fourth and fifth approaches involve comparison of two assemblages (the first three all involve just one assemblage). The fourth involves comparing assemblages across space, while the fifth involves comparing assemblages across time.

Mean and Univariate Descriptions of an Assemblage

Obviously, the greatest possible simplification in describing an assemblage is in reducing Table 1 to a single number. The oldest and simplest such measure is to assess the diversity of an assemblage by counting the number of species, S , present (i.e., species richness). Counting the number of individuals, N , in an assemblage is also common and can be revealing despite its simplicity. Because species richness increases in an inconveniently nonlinear fashion with the number of individuals sampled (Gotelli and Colwell, 2011), a number of measures have attempted to provide sample-size corrected comparators of species richness, including Margalef diversity

Table 1 The most common representation of an assemblage – a list of species, possibly with the abundance of each species included

Species	Abundance N_i	Mass (g) m_i
American Black Duck	1	1200.0
American Kestrel	1	117.0
Killdeer	4	95.0
Barred Owl	1	720.0
Chimney Swift	7	23.0
Ruby-throated Hummingbird	1	3.2
Yellow-bellied Sapsucker	11	50.0
Downy Woodpecker	1	27.0
Hairy Woodpecker	1	66.0
Yellow-shafted Flicker	5	130.0
Least Flycatcher	3	10.3
Eastern Phoebe	10	20.0
Eastern Kingbird	4	40.0
Philadelphia Vireo	3	12.0
Red-eyed Vireo	2	17.0
Blue Jay	4	85.0
American Crow	24	450.0
Tree Swallow	6	20.0
Cliff Swallow	11	21.0
Barn Swallow	16	19.0
Black-capped Chickadee	13	11.0
Red-breasted Nuthatch	7	10.0
White-breasted Nuthatch	1	21.0
Ruby-crowned Kinglet	2	6.5
Veery	31	31.0
Hermit Thrush	2	N/A
Wood Thrush	33	31.0
American Robin	47	77.0
Gray Catbird	6	37.0
European Starling	53	82.0
Northern Parula	2	8.6
Yellow Warbler	6	9.5
Chestnut-sided Warbler	1	9.7
Myrtle Warbler	1	N/A
Black-throated Green Warbler	1	8.8
Black-and-white Warbler	1	10.7
Ovenbird	21	19.5
Common Yellowthroat	9	10.0
Chipping Sparrow	12	12.0
Savannah Sparrow	2	20.0
Song Sparrow	35	20.0
White-throated Sparrow	37	26.0
Rose-breasted Grosbeak	6	45.0
Red-winged Blackbird	9	52.0
Common Grackle	14	115.0
Brown-headed Cowbird	1	44.0
Purple Finch	7	25.0
American Goldfinch	14	13.0
House Sparrow	2	28.0

$S_{\text{Margalef}} = (S - 1) / \ln N$, the Chao estimation of total (including unobserved) species richness $S_{\text{Chao}} = S + S_1^2 / (2S_2)$, where S_1 is the number of singletons (species observed once) and S_2 is the number of species observed twice, and finally rarefaction derived comparisons (Gotelli and Colwell, 2011). The free software package EstimateS provides easy, state-of-the-art access to these methods.

There are also a wide variety of methods that measure the evenness of a community – how similar in abundance the

different species in the assemblage are. As will be seen in the next section (see Variation Within an Assemblage), the short and universal answer is always not very even, but this still allows for potentially interesting variations in degree of evenness between different assemblages. The notion of diversity is intended to capture both richness and evenness (a community of five equally abundant species is more diverse than a community with five species, four of which only occur once). Two common measures of diversity are Shannon's $H = -\sum p_i \ln p_i$ and Simpson's $D = 1/\sum p_i^2$ where p_i is the relative abundance of each species i (i.e., $p_i = N_i/N_{\text{total}}$). These can be turned into evenness measures by dividing by the maximum attainable values (Shannon evenness $J = H/\ln(s)$ and Simpson evenness given by D/S). Dozens of other univariate metrics capturing some aspect of an assemblage exist (Maurer and McGill, 2011).

Treating an assemblage as measured by traits rather than species and abundances can lead to different views. If one wants to provide a simple assemblage-level description of a trait such as body mass or maximum lifespan, some form of mean is the obvious choice. But exactly which mean to report is not as obvious. Firstly, some traits such as body mass are clearly made normal in shape by a log-transformation suggesting that a geometric mean ($\mu = (\prod m_i)^{1/S}$) is more appropriate, although if there is no clear evidence of the appropriateness of a log-transformation, it is probably best to use an arithmetic mean. Secondly, it is not clear whether a species mean, an abundance-weighted-mean, or an individual mean is best. A species mean takes a species-level trait value, $\mu_{\text{species}} = 1/S \sum m_i$ (cf. Table 1). An abundance-weighted mean weights the species trait by the abundance of that species $\mu_{\text{abund-weighted}} = 1/N_{\text{total}} \sum m_i N_i$. Finally, an individual-level mean averages across all individuals: $\mu_{\text{individual}} = 1/N_{\text{total}} \sum m_i$ (where m_i is mass of an individual cf. Table 2). The abundance-weighted mean and the individual mean should be identical only if the species mean trait values are calculated from the assemblage under study. See the legend of Table 1 for reports of common mean and univariate statistics summarizing the assemblage in Table 1.

Table 2 An individual perspective on the same data as in Table 1. Note that each row represents an individual (the full version of Table 2 would have 492 rows for the same data as Table 1). Rather than recording abundance, species with abundance greater than one show up in the table more than once. And rather than using species averages, traits (here body mass) are measured on each individual

Individual band ID	Species	Mass (g)
3719	American Black Duck	1218.2
3824	American Kestrel	109.7
3823	Killdeer	92.1
3783	Killdeer	93.6
3812	Killdeer	97.8
3725	Killdeer	99.2
3765	Barred Owl	720.5
3801	Chimney Swift	22.0
3754	Chimney Swift	24.3
...	...	...

Variation within an Assemblage (Distributions or Histograms)

The last section focused on various attempts to summarize an entire assemblage to a single number, ignoring variation. This section explores descriptions of the variation found within an assemblage but which still simplifies out the details of which species are present. Ultimately ecology and evolution are studies of variation. If there was only one species with clonal copies of an identical organism, there would be no need for the study of ecology or evolution. It is the enormous variation of life that defines both fields. To quantitatively capture this variation, some quantitative property must be identified. One can then describe this trait across the assemblage. The typical way of reporting the variation is to plot a histogram giving the relative frequencies of different trait values. This quantitative description of the variation of traits in assemblages is a central pursuit of macroecology. Before launching into the description of the variability of various quantitative properties of an assemblage, it is useful to address two technical points: the level at which the properties are measured, and introducing the lognormal distribution.

Species Versus Individual Level Distributions

There are several ways to look at properties across an assemblage: one is species centric and one is individual centric. An individual-centric property distribution measures the property on each individual in the assemblage (Table 2 for the property body mass). In contrast, a species-centric distribution measures a property value for each species (Table 1) and then examines the property across all species in the assemblage. Some properties can only be examined in a species-centric fashion since the property is inherent to the species rather than the individual; examples include the abundance of a species, species age, and the size of the species range. But other properties like body mass can easily be conceptualized in either a species-centric or individual-centric approach (White *et al.*, 2007) (Figure 1) (compare Tables 1 and 2). It is a surprisingly under-examined question, which approach is most appropriate. At its heart, the choice ought to be indicative of the level (species vs. individual) at which one thinks the four processes operating on an assemblage apply. A hybrid approach, the abundance-weighted species distribution, serves as a compromise. This approach takes one trait value for each species and then multiplies it by the number of individuals (i.e., abundance) of each species. In practice, the abundance-weighted species distribution is used primarily in situations where an individual-centric distribution is desired but data at the individual level are not available (Figure 1(c)). Whether it is a good approximation depends on how similar the individuals within a species are. It has long been assumed that individuals within a species are more similar than differences between species, but in practice, traits can vary substantially within a species (and often more than between species) (Messier *et al.*, 2010).

Lognormal Distributions

As will be seen shortly, a large number of features of assemblages show a log-normal distribution or something

Figure 1 The distribution of body masses for rodents trapped during one trapping period at Portal, New Mexico (Ernest *et al.*, 2009). The data are the same in all four graphs, but are plotted in different ways. (a) The mass of each individual rodent is used to generate a histogram (frequency distribution). (b) The mean of each species is used to generate a histogram (note the change of interpretation of the y-axis). Plots (a) and (b) are broadly similar (most species/individuals are small with a few very large species/individuals), but some clear differences occur including a smaller proportion of the very smallest animals and more spread around 200 g in the individuals plot (a). (c) An attempt to recreate the plot in (a) using the species averages of (b) and the abundance of each species. It clearly is an inaccurate representation of (a). (d) The same plot as (a) but on a log scale for body mass. This figure looks near to a normal distribution (Gaussian Bell-curve), which suggests the distribution of mass is close to a log-normal distribution.

approximating a log-normal distribution. A variable X shows a log-normal distribution when $\log(X)$ is normally distributed. Lognormal distributions generally appear strongly skewed (asymmetric) when plotted as a histogram on an arithmetic scale. This shows there are a few instances of very large values of X and a great many instances of small values of X . Plotting a histogram on a log-scale removes this skew and reveals something close to a symmetric normal (Gaussian) distribution (Figure 1(d)). There may remain small amounts of skewness (asymmetry) with the left or right side being slightly more predominant. Considerable debate has gone into whether these asymmetries are real aspects of the data (and in which case what causes them) or whether they are artefacts (e.g., sampling biases). The lognormal is a ubiquitous distribution across the sciences (Limpert *et al.*, 2001) describing the distribution of sizes of computer files on a hard-drive (many small files, few large files) to the distribution of income among individual humans (again many low incomes and a few large incomes). The lognormal distribution is generated when many random variables are multiplied together. This makes it hard to identify specific processes for data showing a lognormal distribution (just as we do not attempt to explain why data has a normal distribution). There are a number of other distributions with strong right skew on an arithmetic scale (e.g., the logseries, zero-sum multinomial, zipf-mandelbrot, and power distributions are all commonly used in place of the lognormal distribution). In practice, ecological data are noisy enough that

it is almost impossible to decisively adopt the lognormal in preference to one or more of these alternatives. Thus, the author uses lognormal here as a general description of the overall shape of a distribution while acknowledging that other very similar distributions might fit equally well.

Body Mass Distribution

Body mass of an individual is one of the most basic of all measurable traits. It directly influences resource requirements and it affects the scale at which the individual interacts with the world. In general, body mass is distributed lognormally across an assemblage (Figure 1). Thus, there are many smaller organisms and only a few larger organisms. Body mass was first studied at the species level (distribution of average body masses of all the species in an assemblage) (May, 1988), but has also been extensively studied for individuals (White *et al.*, 2007). May noticed that the distribution was asymmetrical with species apparently missing on the left (small mass) side and suggested this might be due to poorer sampling of small species. Studying individual level assemblages especially makes sense for species which are indeterminate growers (leading to wide variation in body mass within a species) or in which juveniles are predominant. Thus, studies of tree size and plankton size have been especially common at the individual level. For individual-level distributions, it is common to apply the power-distribution and

study the exponent, which often is close to -2 . However, both the species and individual level distributions of body mass are roughly lognormal in nature. Several authors have also shown that the shape of the body mass distribution changes with spatial scale. In particular, as the spatial scales become small enough such that individuals in the assemblage are likely to compete with each other, competitive forces appear to dominate and the lognormal distribution transforms into a log-uniform distribution (a flat histogram on a log scale) (Brown, 1995), which is the probability distribution version of Hutchinsonian ratios of body size.

Abundance (Species Abundance Distribution or SAD)

Another very basic property, which unlike body mass is only applicable at the species level is abundance. How many individuals of each species are there? It is a somewhat surprising but extremely well-established and general fact that there is enormous variation in abundance across an assemblage. Different species of birds in North America vary by seven orders of magnitude of abundance (McGill, 2006). There are typically a few species that are very abundant and many species that are rare. This is suggestive of a skewed distribution and indeed SADs appear lognormal-like (for historical reasons $\log_2$ is typically used) (Figure 2(a), (b), and (c)). This pattern seems to be as close as ecology gets to a truly universal law. A great many attempts have been made to understand which mechanism is responsible for lognormal-like SADs (McGill *et al.*, 2007), but there is a growing consensus that the SAD does not have enough information to differentiate which mechanisms or processes drove community assembly. This is especially true in the context of our growing understanding of how small sample sizes affect the shape of the SAD. Early workers (Preston, 1948) thought small samples simply chopped off the left hand side of the lognormal distribution (a so-called veiled distribution), but recent more mathematically rigorous work shows that the effects are more subtle and varied but that analyzing small samples distorts the underlying distribution (Green and Plotkin, 2007).

The SAD appears to be lognormal-like across all spatial scales. At one extreme is a small community of strongly interacting individuals (Figure 2(a) and 2(b)). As long as the sample size is large enough to be statistically useful (usually at least a few hundred individuals), then a lognormal-like distribution is found. At the other extreme, global SADs look at the distribution of the total number of individuals across the globe for each species in an assemblage (Figure 2(c)). Such global SADs also appear to be lognormal-like, although it has been shown several times that as the spatial scale becomes larger, SADs becoming increasingly more log-left skewed (the left tail of the lognormal distribution becomes heavier) due to the increasing number of transient species detected (McGill, 2003).

Range Size and Occupancy Distribution

Measures of the spatial extent covered by a species are another example of an attribute that makes sense only at the species but not at the individual level. Two common measures are used. One is the size (area) of the geographic range of a

species. This typically conceptualizes a species as occupying a blob covering typically some portion of a continent (or continents) such as those found in field guides, and the area of this blob is the range size. Note that this is different than the home range, the area within which a single individual lives and hunts. Alternatively, one can see whether a species is present or absent at a number of different sites. Then the percentage of sites the species is present in is known as occupancy. Clearly if the sites used are distributed over a large part of a continent, then occupancy and range size would be strongly correlated to each other. However, occupancy can also be applied at much smaller spatial scales, in which case it becomes a measure of how much a species fills in its range or how many different types of habitats a species occurs in.

The distribution of range sizes across an assemblage also show a roughly lognormal (Figure 2(d)) distribution with a few species covering large portions of the globe and most species being much more narrowly distributed. Occupancy shows a different pattern (Figure 3(b)), however. Occupancy is capped at 100% and thus cannot show a long right tail of increasing values. Instead a histogram of occupancies typically shows a roughly U-shaped pattern, with many species with low occupancies, fewer species with intermediate occupancies, and then slightly more species with high occupancies. This U-shaped distribution of occupancy is one of the earliest patterns to be documented as being generally true of all assemblages (Raunkiaer, 1909).

Traits and Trait Distributions

One can imagine measuring the distribution of a number of other traits across an assemblage. For example, one could measure the distribution of life history traits such as maximum life span across an assemblage. Or one could measure functional traits such as maximum metabolic rate (in an animal) or maximum photosynthetic rate of a leaf (in a plant). The idea of a trait is increasingly gaining traction in ecology and is defined as some quantitatively measurable aspect of an individual that is thought to be of significance to the organism. Two broad categories of traits are functional traits, which are measurements of features that have a direct relevant to performance and fitness such as photosynthetic rate or leaf mass per unit area (basically leaf thickness) and life history traits, which describe the overall allocations to survival and reproduction of an organism such as age of first reproduction or maximum life span. Relatively little study has been made of the assemblage-wide distribution of such traits. One thing that seems clear is that assemblages show a great deal of variation in traits not only between species but also within species. Variation within a single assemblage captures a large fraction of all global variation in a trait (Messier *et al.*, 2010). However, general expectations about whether traits are distributed normally or lognormally or otherwise have not yet been developed (Figure 2(e) and 2(f)).

Covariation (Correlation) within an Assemblage

The last two sections covered patterns addressing a single variable measured across an assemblage. This effectively

Figure 2 The frequency distribution (histogram) of several species-level properties of assemblages of birds found from the North American Breeding Bird Survey (Sauer *et al.*, 1997). (a) The distribution of species abundances for a single route at 45.05N, 69.033W near Orono, Maine. There are many rare species (species with few individuals) and only a few very abundant species. This is a local species abundance distribution. (b) The same data as (A) plotted on a logarithmic scale (plots for species abundance distributions traditionally are plotted on a log-base-2 scale). This is approximately normal (implying a lognormal distribution) but there is an excess of singletons (species with only one individual). (c) A $\log_2$ plot of total species abundances across all routes in the entire region covered by the North American Breeding Bird Survey (the continental US and southern Canada). This represents a global species abundance distribution. It is similar in shape to the local distribution (b). (d) The frequency distribution of range sizes of species on an arithmetic scale (which is similar in shape to (a) and is also approximately lognormal). (e) Frequency distribution of LMA (Leaf Mass per unit Area). The distribution at four different plots labeled by compass directions is shown. Note how the frequency distribution of this trait remains very similar across different plots (despite having very different sets of species in each plot). LMA is a commonly measured plant functional trait that measures leaf thickness. It is strongly positively correlated with leaf lifespan. Note that this functional trait is distributed nearly normally. (f) Frequency distribution of maximum life span (in months) of mammals (Ernest, 2003). Note that in contrast to (e) this trait is distributed in a fashion approaching lognormal.

assumes every property of an assemblage is independent of every other property, and more specifically that each property can be examined in isolation. In practice, trade-offs and allocation strategies often result in strong interactions between properties within an assemblage. These are most commonly studied using a correlation or regression approach. As before, these correlations sometimes occur at

the species level and sometimes occur at the individual level.

Energy versus Mass

One of the oldest known linkages between two traits is between the body mass of an individual, M , and the amount

Figure 3 The relationships between various properties of individual species within an assemblage (except Figure (b)). (a) The relationship between body mass and energetic flux (metabolic rate) known as Kleiber's law. (b) A frequency distribution of occupancies in trees in a 50 ha plot on Barro Colorado Island, Panama (Condit *et al.*, 2000). Compare with Figure 2(d). This plot also shows many species with low occupancy, but in contrast shows many species with high (near 100%) occupancy. This is due to the truncated scale of occupancy (occupancy cannot go higher than one). (c) The relationship between abundance and occupancy in the same data as (b). There is a positive correlation between abundance and occupancy with very low abundances having occupancies close to zero and very high abundances having occupancies of 1.0 (100%). (d) The relationship between abundance and range size in the North American Breeding Bird Survey (Sauer *et al.*, 1997) (here measured by the total number of routes a species is observed on). There is a positive relationship, but there is considerable variation. (e) The relationship between body mass and abundance of species in the same dataset as (d). The relationship is negative but very noisy. (f) The same data as (e) plotted at the taxonomic level of family rather than species.

of energy consumed, E . Kleiber (1947) showed that among mammals, $E = cM^{3/4}$ (Figure 3(a)). This is known as the mouse-to-elephant curve as it places the energy consumption of species as small as a mouse and as large as an elephant on a single standardized curve. Later work has extended the link between mass and energy by showing that this pattern appears quite general. Different groups of organisms may have a different value for the constant, c , with high energy requirement groups like birds having a higher c , and low energy requiring groups like reptiles having a smaller c , but the exponent is always very close to $3/4$. Amazingly, it is possible to place all species from single-celled organisms to blue whales on a single curve with $E \propto M^{3/4}$. Plants also follow $3/4$ scaling although it is not common to measure plant mass, leading to other exponents such as the scaling of energy with diameter at breast height (DBH) as $E = c(\text{DBH})^2$. One of the most surprising aspects of this rule is the extremely high amount of variance explained, often having $r^2 > 0.95$. A number of recent studies have begun to show that $3/4$ scaling may not hold at the margins such as for young plants (Muller-Landau *et al.*, 2006), prokaryotes (DeLong *et al.*, 2010) and the smallest mammals (McNab, 1986). These seem to be exceptions that prove the rule, however.

The $3/4$ scaling of energy flux rates in turn seems to drive a number of other closely related factors (Calder, 1984). For example, production (growth in body size plus mass of offspring) appears to scale as $M^{3/4}$. Amazingly, other factors still more distantly related to energy flux such as the population growth rate, r , also scales as $M^{3/4}$ although the amount of variance explained goes down as one gets more removed from pure energy flux. Note that the energy flux per unit mass ($\propto M^{3/4}/M = M^{-1/4}$) scales as $M^{-1/4}$ so larger animals have less energy flux per unit mass. Thus, an elephant has more total energy fluxing through its body than a mouse, but has less energy per unit mass (and effectively per unit volume). One important implication of this is that drug dosages usually scale as $M^{3/4}$, thus a human who weighs twice as much as another human does not need twice as much drug but rather $2^{3/4} \approx 1.68$ times as much drug. Also, note that energy has units that include seconds in the denominator (s^{-1}) so one might suspect that the reciprocal of mass-specific energy (which is proportional to $M^{-1/4}$) would give the scaling of time, and indeed, many time based measures such as time between heart beats or average life span scale as $M^{1/4}$. An interesting sidenote is that this means that the total number of heartbeats is proportional to lifespan divided by time-

between-beats $\propto M^{1/4}/M^{1/4} \propto M^0$ suggesting that the total number of heartbeats in a lifespan is a constant across a group such as mammals.

There are a number of theories to explain 3/4 power scaling. The oldest theory, which noted that surface area increases as length² while mass increased as length³ predicted a $M^{2/3}$ scaling. While 0.667 is close to 0.75, there seems to be clear evidence that 2/3 scaling is not correct and that while there is noise in the exponent, the results clearly center on 3/4. A recent paper (West *et al.*, 1997) suggested that 3/4 scaling is a result of fractal branching networks used to distribute the key components of energy (e.g., blood vessels, xylem tubes). This model makes a number of assumptions and a number of predictions about fractal branching networks, which have not yet been decisively tested. Several other explanations have emerged recently including a theory based on a different type of distribution network, an exploding network (Banavar *et al.*, 2010), on a general comparison of space (3-dimensions) versus lifetime (4 dimensions including time), and an argument that different systems (vascular, pulmonary, renal, etc.) each have their own scaling exponent all of which are bounded between 2/3 (for the reasons given above) and 1, but which average out to about 3/4 (Darveau *et al.*, 2002). More work is needed to decisively test which of these mechanisms are central.

Abundance Versus Occupancy/Range-Size

Another pair of variables that are often linked to each other are abundance versus measures of spatial extent (range size or occupancy depending on the scale of measurement). In general species of high abundance occupy larger areas (Figure 3(c) and 3(d)). However, care must be used to avoid circularity. For example, global abundance will be trivially correlated with the number of sites a species is found at. The most careful approach is to use average abundance at all sites where the species is observed (i.e., average all nonzero abundances across sites for a species), which eliminates such statistical artifacts. This measure still tends to have a strong positive correlation with range size and occupancy. The abundance–range size relationship has a good deal of noise (Figure 3(d)). In contrast, the abundance occupancy relationship (Figure 3(c)) is fairly tight and can be made even tighter when correcting for the fact that species are clumped in space (Conlisk *et al.*, 2009). Thus, while in principle different aspects of rarity such as abundance and range size used as criteria for listing a species as endangered can vary independently there is a propensity for these aspects to be correlated.

Abundance Versus Mass

As already seen, body mass is strongly correlated with energy flux and ultimately with resource requirements. Thus, one might expect that the size of a population that could be supported might be related to body mass and that body mass could then be predictive of the widely varying abundances of different species in an assemblage. A simplistic guess would be that each species would consume the same amount of energy. This suggests that the number of individuals, N , times the

energy requirements, $E = cM^{3/4}$ multiplied together to give the total energy usage by a species would be a constant – i.e., $k = NcM^{3/4}$. Solving this for N and combining constants we get $N = cM^{-3/4}$. Although this model is based on the bold assumption of equal energy per species, there is some evidence that it holds (Damuth, 1987). This pattern seems to hold most strongly when data are chosen to make sure that the assemblage studied is all from a single trophic level (e.g., mammalian herbivores) and that measures of maximum or global abundance are used. This model is usually applied at the species level, but can be applied at the individual level by using bins of different size classes (Cyr *et al.*, 1997; Enquist *et al.*, 1998). However, the current consensus (McGill, 2008) suggests that many organisms do not follow this precise law, showing a negative scaling exponent (large organisms are less abundant than small organisms) but an exponent greater than $-3/4$, suggesting that large organisms capture larger proportions of the total resources consumed by an assemblage (Figure 3(e)).

Abundance Versus Other Traits

The orders of magnitude variation in abundance across different species in an assemblage remains a striking pattern demanding explanation. As a result, there have been many studies seeking to find traits of a species that will predict its abundance relative to other species in the assemblage. In short what traits make a species common or rare? Factors such as dispersal ability, vegetative versus sexual reproductive modes, ability to enter dormant states, etc. have all been explored (Murray *et al.*, 2002). To date, though, this research program has had little success with no predictors that seem consistent across different studies and no predictors that explain significant proportions of the variability in abundance (beyond the already mentioned weak relationship to body size and range size). One reason for this is that most studies use local measures of abundance, but it is known that a single species will show considerable (usually orders of magnitude) variation in abundance across space. Thus, comparing abundance from a randomly chosen site (and thus essentially a randomly chosen abundance for the species) versus a trait will have considerable noise. It is possible to turn this around and use the spatial structure of abundance for a single species across space to predict abundance: distance from a species' peak abundance is one of the better predictors of relative abundance in a community (McGill and Collins, 2003). Going forward, any attempts to find species-level traits that correlate with abundance should use a species-level (i.e., global) measure of abundance. It is well known that abundance is a very labile feature in phylogenies, meaning that species that are evolutionarily close to each other can have widely varying abundances or equivalently that evolutionary proximity is a poor predictor of abundance (McGill, 2008). Understanding what factors make a species abundant or rare remains a major unsolved problem.

Traits Versus Traits

One can look at the covariation within an assemblage of any two traits. When positive correlations are found, this is often

indicative of some common underlying factor driving both traits. When negative correlations are found, this is often indicative of trade-offs. For example, the recent discovery of the leaf economic spectrum has shown that a suite of leaf functional traits are related. Leaf thickness (or leaf-mass-per-unit-area) and leaf life span are positively correlated with each other, as are maximum photosynthetic rate per unit mass, nitrogen and phosphorus concentrations (mass based) while the two groups are negatively correlated; the first principle component explains 74% of the variance (Wright *et al.*, 2004). Proximally this may well be driven by the common underlying factor of how much investment in structural material is made in the leaf. A more ultimate cause may be trade-offs in leaf investment in environments with high- or low-leaf mortality. In contrast, there are negative correlations between root biomass and shoot biomass within a single species (a plant has to choose how much energy and nitrogen to invest to each component).

Similar patterns can be found in life history traits. Maximum life span and age at first reproduction are positively correlated with each other but negatively correlated with measures of fecundity per unit time. This leads to the notion of a fast-slow spectrum. Some species live a weedy life style of growing quickly, reproducing early and often and dying young, while other species live long lives with slow reproduction and investment into high quality young. Broadly life span and fecundity are negatively related because allocation to fecundity reduces allocation to maintenance functions.

Variation between Assemblages Across Space (β Diversity)

The previous three sections explored patterns within a single assemblage (a set of individuals and species at a single location). It is also interesting to explore how similar or different assemblages are as one moves across space. By definition when comparing two locations, one is comparing two distinct assemblages. But these two assemblages could be very similar or quite different to each other. Tobler's First Law of Geography suggests that two assemblages that are closer to each other should be more similar than two assemblages that are far apart. The quantitative study of these questions is a field known as β (beta) diversity.

It is generally recognized that all five of the processes driving assemblages are involved in creating β diversity. Some difference is created by dispersal limitation – the fact that individuals' in one assemblage cannot easily disperse into a new assemblage in a new location. If there were no dispersal limitation and assemblages were connected by an infinite amount of dispersal then all assemblages would be identical (or more precisely, all differences would be due only to finite sampling effects). If there is an underlying environmental variability, possibly arranged along a gradient or possibly arranged in a patchy fashion then deterministic abiotic filtering will cause species assemblages to differ at points in space with different environments. This of course can then create differential biotic filtering across space, which can further exaggerate assemblage differences. Finally, when one moves across spatial scales so large that the assemblages have experienced different

evolutionary histories and thus different regional source pools, the assemblages must necessarily differ.

Three Ways to Describe β Diversity

There are broadly three ways to characterize β diversity. On the surface they appear quite different, but they are in fact capturing the same underlying processes – the change in the make up of assemblage as one moves across space. The simplest method and the origin of the term " β diversity" comes from Whittaker (1975). Whittaker described a situation where one looks at a small plot embedded in a much larger region. Following this hierarchy, at the small end one has α diversity (e.g., species richness) of a single plot (in practice usually an average of richness across all plots) and at the large end of the hierarchy one has γ diversity as the diversity of the entire region. β diversity is what is left in the middle, specifically β diversity is the difference between the γ and α diversity (specifically $\beta = \gamma - \alpha$ or originally $\beta = \gamma/\alpha - 1$) (see Figure 4(d)). In practice, β diversity is the difference between the plots. If each plot has an identical set of species, then β diversity is zero. If each plot is slightly different from other plots in assemblage composition, then β diversity is a bit above zero and so forth to the extreme case where every plot has a different set of species in its assemblage giving maximum β diversity.

A second way of describing β diversity is to plot a species-area relationship (Rosenzweig, 1995) – a plot of species richness, S , versus plot size/area, A . Typically a species-area relationship is plotted on a log-log scale and is approximately a straight line, implying the species-area relationship is well approximated by a power-law relationship, $S = cA^z$ (Figure 4(a)). The steeper the slope of the species-area relationship (the value z on a log-log plot), the more rapidly new species are encountered as one expands the sampling area, and the higher the β diversity. When very large ranges of spatial scales are plotted, a tri-phasic (steep/shallow/steep sloped curve) is found (Figure 4(b)). This is often interpreted as indicative that different processes are involved in driving the species-area relationship at the three different scales (see Sampling Scale, and Habitat and Dispersal Limitation Scales, and Biogeographic Scales) (Rosenzweig, 1995).

The third way of describing β diversity is to use a measure of similarity between pairs of plots. First one needs a definition of the similarity between two sites. As with species diversity, there are dozens of proposed metrics. Two of the most common are the Jaccard similarity and Sorenson similarity. Jaccard similarity is the number of species in common between two assemblages divided by the total number of species across both systems. Sorenson similarity is the number of species common between the two assemblages divided by the average number of species across both plots. These measures use only information on whether a species is present or absent in an assemblage. An even more nuanced view can be used by looking at abundances, rating two assemblages as less similar if a species is very common in one assemblage and rare in the other even if it is present in both. One common metric for this is the Bray-Curtis measure. Let N_{ij} be the abundance of species i in community j . Then the Bray-Curtis index of

Figure 4 Different ways of reporting β diversity (change in species composition of assemblages across space). (a) Species–area relationship for birds. Each point is one island in the Caribbean ranging from Grenada to Cuba (Preston, 1962). (b) A species–area relationship for birds of North America (Preston, 1960). Note that as the spatial scales covered expand, a more complex pattern than observed in (a) emerges – namely the curve becomes “tri-phasic” (steep slope, shallow slope, steep slope). (c) A plot of the decay of similarity of distance for the North American Breeding Bird Survey (Sauer *et al.*, 1997). (d) A plot of a hierarchical partitioning of diversity for the same data as (c). Each route has a diversity of 75.7 species (on average), which is α diversity. The total system (all of North America) has 600 species. This is reached by an average increase of diversity of 52.0 (to 125.7 species) within each stratum (the BBS classification of ecoregions). In contrast 472.2 new species are picked up by moving between strata. Thus, most of the diversity in the BBS occurs between different ecoregions and secondarily within a single route. Comparing routes (assemblages) within an ecoregion adds comparatively less diversity.

similarity is $2 \sum_i \min(N_{i,1}, N_{i,2}) / \sum_i \sum_j N_{i,j}$. Given a measure of similarity, one can then plot similarity as a function of distance, which is known as a decay-of-similarity-with-distance plot (Figure 4(c) and 4(d)). It typically shows something approximating exponential decay. This again describes how quickly species change as one looks at larger areas. Thus, all three approaches capture the same underlying process – different areas contain different sets of species. However, the first two methods (hierarchical and species–area relationship) look only at the addition of new species as area is added, while decay of similarity looks at differences between assemblages due to new species (as in the first two approaches) but also to species disappearing as area expands. Formal mathematical links between these three views of β diversity have been derived (Koleff *et al.*, 2003; Anderson *et al.*, 2011).

There are very few patterns known to be general about β diversity. It is likely that nowhere on earth has zero β diversity (i.e., where assemblages at different locations in space are all the same). Certain taxonomic groups tend to have lower β diversity, usually groups that have outstanding dispersal abilities such as bacteria or ferns, but even these groups do not show zero β diversity. Much β diversity is driven by underlying spatial change in the environment (Buckley and Jetz, 2008). There is growing evidence that human-built environments (cities, agriculture) tend to greatly reduce

β diversity even though humans do not necessarily decrease α diversity (species richness of individual assemblages). Like most patterns about assemblages, the structure of β diversity depends on scale (Lennon *et al.*, 2001).

In the section Variation Within an Assemblage (Distributions or Histograms) we had a good understanding of the patterns, but a poor understanding of the processes. In contrast in this section on β diversity but we do not have a good understanding of the patterns in β diversity, but we do have a fairly good grasp of what the dominant driving processes are at different scales.

Sampling Scale

At the smallest scales (the area occupied by a few individuals – as small as a few centimeter for grasses to tens of meters for trees to many kilometer for some top predators), the main determinant of β diversity is just random sampling. A given location could be filled by individuals from many species, but at any one time only one individual can fill it (this is most obvious in plants). Thus, the chance event that determines which individual gets there first and establishes is the dominant factor. Microsite variation in topography, soil pH, etc. (some of which may be driven by the organisms) may play

some role, but stochasticity predominates. Thus, if we compare the “assemblage” at two sites (assemblage is in quotes here since assemblages at this scale consists of only one individual and thus one species) the differences will be stochastic, and the best predictor of the likelihood that both individuals will be from the same species is their relative abundances at regional scales (more abundant species are likely to be found at both sites). Sampling processes are clearly involved in the first steep portion of the triphasic species–area relationship (Figure 4(b)) and perhaps part of the second flatter portion.

Habitat and Dispersal Limitation Scales

Beyond very small scales, pure random sampling does not generate realistic levels of β diversity (McGill, 2011a). However, β diversity at intermediate scales are well-modeled if one models nonrandom sampling where individuals of a single species tend to come in clumps. Specifically to accurately predict β diversity at scales of kilometers it is necessary to know two things: not only the relative abundance of species (as in the sampling scale above) but also an understanding of the degree to which individuals of a species are likely to be sampled at the same time. If an individual of species *X* is sampled into assemblage *A*, then additional individuals of species *X* are more likely to be sampled again (than its relative abundance would suggest) into assemblage *A*. There are two main reasons for this clumping or correlation of individuals within a species. One explanation is habitat heterogeneity. As one moves across the landscape at scales of hundreds of meters to kilometers, one moves across riparian habitats, forests, meadows, etc. as well as smaller variations such as upland forest versus lowland forest. These habitats are driven by a combination of topography and disturbance history and strongly influence which species are most likely to settle there. This can cause individuals of a species to be more likely to co-occur in an assemblage than suggested by random chance. The second reason that we see this co-occurrence within an assemblage or clumping is dispersal limitation. Dispersal across space is in general a costly proposition. As a result, offspring generally are located close to their parents. This phenomenon is known as dispersal limitation and can result in amplifying chance locations of founding individuals, such that if one individual of species *X* happens to end up in the area covered by assemblage *A*, many of its offspring are also more likely to end up in the area of assemblage *A*. The effect of the increased probability of co-occurrence within a single assemblage *A*, is to make pairs of assemblages more different from each other. Thus, if species *X* is more common in assemblage *A* than expected by random chance, it is likely that in assemblage *B*, some other species *Y* is more common than expected by random chance, either because assemblage *B* occurs in a somewhat different habitat or because the random founder effects preceding dispersal limitation are different in assemblage *B*. Thus, at these intermediate scales ranging from the scale of a few dozen individuals (many meters) to large populations the two factors of habitat heterogeneity and dispersal limitation seem to make assemblages more different from each other than we would expect from random chance

alone. These two factors appear to be associated with the middle or flat phase of the triphasic species–area relationship (Figure 4(b)).

Biogeographic (Climate and Evolution) Scale

At truly large spatial scales – hundreds to thousands of kilometers – the primary driver of β diversity becomes the geographic ranges of species. Indeed for birds (McGill and Collins, 2003) and trees (McGill, 2011a) it would appear that for any sample bigger than about a 100 km × 100 km square, all species whose geographic range covers that square will show up somewhere in the square. Thus, the processes controlling geographic ranges become the dominant process. In this case turnover is caused by moving out of the geographic range of some species and into the geographic range of other species. The β diversity between two assemblages *A* and *B* is driven by which geographic ranges assemblage *A* fall into and which geographic ranges assemblage *B* falls into. Our current understanding of species ranges suggests that two main forces control them. One is climate – many boundaries of many species ranges are set by fairly clear climatic constraints. These may include obvious factors like freezing temperatures or total rainfall but can also include more subtle factors such as the seasonality of precipitation or on very specific details such as in the case of the saguaro where below freezing temperatures last for longer than 12 h. It also seems that deep-time evolutionary processes are important. The act of speciation creates new species. Presumably evolutionary forces drive the wide variation in size of small to large-ranged species. And vicariance events – the dispersal of a species from one continent or biogeographic province to another (a form of dispersal limitation but on a rather different temporal and spatial scale) clearly play a role. Beyond these generalities, our understanding of what creates and maintains species ranges is fairly weak and needs more development. To look at β diversity that uses abundance (e.g., Bray–Curtis index) rather than presence/absence data (e.g., Sorenson), one can replace geographic ranges with the idea of abundance surfaces (Figure 5(a)) (McGill and Collins, 2003). Abundance surfaces are effectively 3-dimensional geographic ranges with the third dimension (height) representing the abundance of a species at each point across its geographic range. Then abundance-based β diversity is driven by processes that affect species ranges and the abundance surfaces on them. Even less is known about what factors drive abundance surfaces than we know about what drives geographic ranges. But broadly the main drivers are likely climate and evolution, and these processes are the main drivers in the third, steep phase of the triphasic species–area relationship (Figure 4(b)) and possibly some of the second flat phase as well.

Variation in an Assemblage Over Time (Dynamics)

Just as one can compare two assemblages at different points in space, one can also compare the assemblages from one spatial location at two different points in time. And one finds that the

Figure 5 (a) An abundance surface for the Dickcissel derived from the North American Breeding Bird Survey data. The remaining figures look at β diversity in time instead of space. Similar plots can be used. (b) A species–time relationship (same as species–area relationship with time substituted for space) can be plotted. Compare with [Figure 4\(a\)](#) (a species–area relationship). The data source is the same as [Figure 2\(c\)](#) covering the years 1975–2007. (c) The same data as (b) but plotted as a decay of similarity with distance over time. Note that unlike space, the exponential decay curve is not a good fit – similarity drops too fast in short time periods (representing noise between years) while in long time periods similarity has not decayed as fast as exponentially, representing some long-term stability once the short-term noise has been accounted for. (d) Another decay of similarity with time but over a much longer time span requiring a log-scale on the x-axis. Data are of small mammal bones found in wood rat middens.

species composition found at a fixed spatial location changes over time with species appearing and species disappearing and the relative abundance of species changing. There is an increasing awareness that the patterns that emerge from such comparisons are very similar to the patterns found in space and that many of the same processes are involved. Thus, increasingly ecologists are talking about β diversity in time and using the same tools (species–time relationships instead of species–area relationships and decay of similarity with time curves instead of decay of similarity with distance) ([Figure 5\(b\)–5\(d\)](#)). There is one fundamental distinction, which is that if the time intervals are short enough, the individuals being counted in the two assemblages may in fact overlap (individual X is counted in the assemblage at time A and the assemblage at time B). At longer time scales (i.e., the time of a couple of generations) the same individuals will not be counted, but the offspring of the original individuals will be counted. Thus, temporal β diversity tends to have an inherent mechanism that ensures that change in species composition shows more inertia. But beyond this many of the same mechanisms including sampling, dispersal, habitat preferences, climate, and evolution can play similar roles as the time scales increase.

Species–Time Curves and Temporal β Diversity

As with spatial β diversity, the same three different perspectives (species–time, temporal scale partitioning, and decay of similarity with time curves) can be used to describe what is the same basic underlying phenomenon of change in species composition over time. The first tool used was the species–time relationship ([Figure 5\(b\)](#)), but all three methods have been used. The species–area–time–curve allows one to find an equivalence between space and time. For example, Alder and colleagues found that an equivalent amount of turnover occurs in 1 year or 50 m² for Kansas plants, 1 year or 1 ha for small mammals, and in the very long dispersing short lived plankton, 5000 km² is needed to match the new species found in 1 year ([Adler et al., 2005](#)). Decay of similarity with time curves ([Figure 5\(c\)](#) and [5\(d\)](#)) seem similar to the equivalent spatial patterns but with a subtle difference – there seems to be a faster than exponential drop in similarity in very short time frames. This suggests a system with an innate level of noise (causing rapid drops in short time scales). As with spatial β diversity, the causes and dominant processes change with scale. The author examines four temporal scales here.

Sampling and Detection Scale

At the smallest temporal scales (less than one generation), the assemblage being sampled at time *A* and time *B* is essentially the same assemblage – any differences are due to sampling and detection errors of the survey methods. This is not a particularly biologically interesting scale or process, but it does present a baseline for the amount of turnover due to sampling noise that can then be used to demonstrate that larger amounts of turnover at longer time scales must be due to more interesting biological processes. Obviously the amount of noise at this scale depends on the organism and the survey methods. Stem-mapped tree plots will have almost no noise and turnover at this scale, while birds identified by sight and sound in quick point counts could show significant turnover due to sampling and detection errors.

Population Dynamics Scale

At the next largest time scale (one to a few dozen generations), population dynamic processes play an important role. Classic differential equations such as the logistic and Lotka-Volterra equations are used to describe how populations change over time. However, these populations assume a constant environment and a closed system. In reality population dynamics show considerably more fluctuation due to immigration and emigration from the population as well as external forcing factors that change from year to year including the weather, the abundance of competitors and predators, and the amount of food available. As an example, extreme drought or frost years relative to the norm for a given location can cause major diebacks and drastically change the species composition.

Climatic Forcing Scale

At even longer time scales (thousands to hundreds of thousands of years) there can be trends in climate. These trends in climate can drive major changes in species composition as species track their optimal climates across the continent. Using various fossil assemblages such as tree pollen and diatoms preserved at the bottom of lakes, small mammal bones and plant macrofossils (leaves and sticks) preserved in packrat middens and fossil corals scientists have been able to track the changing composition of assemblages over timescales of thousands to hundreds of thousands of years at one location in space. These data sources make it clear that between about 20,000 years ago (the last glacial maximum) and 10,000 years ago (when temperatures stabilized at approximately what they are today) there was very high turnover (change in a majority of the species) at many locations. What is less clear is what happens to an assemblage. Assuming a group of species are together in an assemblage at time *X* at location *A*, will the same assemblage of species be found at some future time *Y* at location *B*, or will the assemblage be broken up? Conventional wisdom, focused on plants suggests that the assemblage will be broken up, causing not only the movement of assemblages but also the reassembly of new assemblages never seen before. This is known as a nonanalog community

or assemblage (Williams *et al.*, 2001). However, other studies have shown that assemblages remain largely intact over hundreds of thousands of years (i.e., inertia) (Figure 5(d)) (Pandolfi, 2002; McGill *et al.*, 2005). The relative importance of inertia versus nonanalog communities in different communities is an open question.

Evolutionary Scale

Over timescales approaching a few million years, assemblages show change due to macroevolution. Species go extinct and speciation creates new species. Ultimately the species richness of an assemblage is determined by a balance between speciation and extinction events (Rosenzweig, 1975). A number of factors are known to affect speciation and extinction events including the number of currently existing species (a form of density dependence) (Rosenzweig, 1975) and periods of climatic transition. The relative importance of sympatric versus allopatric speciation (and the relative role of geology/topography vs. climate in the latter) is also being actively debated. The evolution of the distribution of traits is also studied. For example, in body size there is good evidence that the mammals have greatly increased the variance (dispersion or width of the distribution) with some debate remaining about whether the mean has increased or remained the same as when the clade started (Smith *et al.*, 2004). Body size has also changed in response to temperature (increasing in cold temperatures and decreasing in warm temperatures).

Assemblage Properties and Global Change

The sections Mean Descriptions of an Assemblage, Variation Within an Assemblage (Distributions or Histograms), and Covariation (Correlation) Within an Assemblage, have focused on basic research questions about assemblages: what patterns are there and what processes underlie these patterns? However, this knowledge about assemblages is increasingly being applied to the modern human-caused biodiversity crisis. There are at least three broad ways in which knowledge of assemblages can be useful in this applied context: indicators, filling knowledge gaps, and baselines.

Indicators

Extreme human impacts such as clear cutting, building roads, or plowing fields have rather obvious impacts on the natural ecosystem, allowing for an informed debate about the pros and cons of such development in a particular situation. However, many development and management practices are much more subtle. Such practices include exurbanization (low-density housing development outside the suburbs), selective logging, roads in wild areas, etc. The ecological consequences of such actions can often be subtle and even counterintuitive. For example, clear cutting that leaves behind patches of original forest habitat can actually increase species diversity in the retained patches in some cases and for some taxa, but this is mostly because it mixes forest with edge

species. More nuanced measures of the impact of ecosystems are clearly needed. Advanced multivariate statistics are clearly one approach. But such approaches have limited available expertise within the scientific community and great difficulty in translation to managers and policy makers. The tools of describing assemblages given in this entry can provide a useful toolkit for measuring changes.

Figure 6 provides two examples of using assemblage descriptions as indicators as applied to a breeding bird survey route in late secondary forest. **Figure 6(a)** builds on the techniques from the section Mean Descriptions of an Assemblage, and also from a recent study, (McGill, 2011b) which showed that using three distinct univariate measures, one to represent total assemblage abundance, one to represent total assemblage diversity and one to represent assemblage evenness provided a good description of assemblages and separated multiple assemblages well in ordinations. Specific measures depend on sampling methodologies and sizes. **Figure 6(b)** builds on the techniques of the section Variation Within an Assemblage (Distributions or Histograms) by using a particular way of plotting species abundance distributions to control for total assemblage abundance and richness and which highlights the proportion of rare species in the assemblage. Both figures suggest that this assemblage initially improved and then leveled off to a noisy equilibrium by several key indicators of healthy ecosystems (higher richness, abundance, evenness, and proportions of rare species). Other aspects of assemblages can be tracked as well. For example, studies of fisheries show that the average mass of individuals being caught and the average trophic level (as measured by isotope analysis) have decreased over recent decades. The relative proportions of different size classes (basically the frequency distribution of body size) can be an important indicator of successional stage in forests and an indicator of ecosystem health. Some studies have also shown that α diversity may increase or be unchanged under human disturbances, but the β diversity may drop considerably – in short humans are homogenizing the landscape, which will reduce overall (γ) diversity even if simplistic α -diversity measures fail to show this.

Knowledge Gaps

Another use of our knowledge of assemblages is to fill in sparse information about endangered species. A few charismatic endangered species such as the grizzly bear or panda bear are extremely well studied but most endangered species including not just plants and insects but even vertebrates like birds in the tropics are poorly studied. Conservation action plans may be needed even before studies on the many thousands of endangered species can be performed. Our expectations about assemblages can be used to provide approximate but very quick answers to fill in these knowledge gaps. One good example is the link between body size and many other factors such as maximum rate of population increase (r) or offspring size or clutch/litter size (mediated by the link between body size and metabolic rate (see Covariation (Correlation) Within an Assemblage)). Two papers use such relationships to expand our knowledge about poorly known

Figure 6 Two examples of how our understanding of assemblages can be used to help in assessing human-caused impacts on assemblages. Both datasets are for birds (see **Figure 5(b)**). (a) Each point represents one year (1975–2007) with darker points representing later years. A simple ordination is performed by plotting these points vs. species richness, total abundance and evenness (McGill, 2011b). Overall the system has moved from low richness and high abundance to the opposite (high richness and low abundance), then returned to settle around a region intermediate in both abundance and richness. Evenness has also increased. This suggests that this one site near Orono ME has actually shown improvement especially from the 1970s to the mid 1980s, possibly with some overshoot but appears stable at the present time. (b) The same data plotted as species abundance distributions. This plot is a new way of plotting species abundance distributions (McGill *et al.*, 2007). The x-axis shows abundance as a percentage of all individuals in the assemblage (i.e., relative abundance) on a log scale. The y-axis shows the percentage of species with an abundance equal or less than that shown by where a horizontal line intersects the curve. Thus, for the dark 2005 line, 80% of species have an abundance of 2% or less. As a result rare species appear on the left side and common (high relative abundance) species appear on the right, making it easy to determine the relative proportions of rare species (higher line on the left side). This graph allows for easy comparison between assemblage with different numbers of species or individuals. This data suggest that the proportion of rare species was lowest in 1975 and 1981, generally increased, with an extreme deviation in 1993 and is the highest it has ever been in the last year of 2005. Again this is suggestive of an assemblage that has become less detrimentally impacted by humans in the past 35 years.

dinosaurs (Farlow, 1976) and endangered tropical birds (Pereira *et al.*, 2004).

Species–area relationships provide a quick tool to estimate the approximate effects of reducing the amount of available

habitat (if a species area curve is calibrated for an area and ecosystem, then the number of species can be read off for the projected new, smaller area). Traditional reserve design (deciding which areas of land to set aside for conservation purposes) has focused heavily on α diversity by building parks in the areas of highest α diversity (so-called hot spots of diversity). However, assessing trade-offs such as more small reserves versus fewer large reserves depends on understanding the β diversity in the system. Understanding the factors that drive β diversity (habitat variability and climate variability) can help us to predict the likely β diversity for many more taxa than what we could feasibly measure β diversity for.

Historical Range of Variability

One of the major shifts in our understanding of ecological systems in recent decades has been the growing appreciation of the continuous presence of variability. Stable unchanging systems do not occur naturally. Thus, the mere act of observing that an assemblage has changed neither proves that humans have caused the variation nor does it tell us whether the change is large. Knowing what the historical range of variability is (i.e., how much temporal β diversity there is) helps us answer these questions. It gives us an immediate scale for how much change is “normal”. This especially holds true if we have records of the system from before humans were impacting the system, either from paleontological data or from long-term record keeping starting when human impacts were low. As one example, we know that the amount of global warming expected in the next couple of centuries is on the same order of magnitude as the changes from the last glacial maximum to present conditions. This tells us that human-induced climate change is large relative to historical levels of variation. However, the fossil record also tells us that in many parts of the world extinctions in response to this climate change were almost nonexistent. In North America, no small mammals went extinct and only one species of tree went extinct over two million years of over a dozen glacial cycles. This suggests that climate change alone is survivable by ecosystems (although unfortunately it also tells us that tracking climate change was the main survival mechanism, and tracking climate may be significantly harder for species to do in the modern fragmented landscape humans have created). In other systems we have so far exceeded natural historic variability (e.g., increases in CO₂ in the air relative to historic levels in the last several thousand years) that there can only be something unique in history and likely human caused going on. Knowing the historical range of natural variability can be an important step in understanding the role of humans.

Conclusions

The study of assemblages of species is one of the basic areas of study in ecology. There has been an explosion of research on assemblages in recent decades. We are increasingly able to summarize and simplify our descriptions of assemblages (see Mean Descriptions of an Assemblage and Variation Within an Assemblage (Distributions or Histograms)), understand the

patterns of structure within an assemblage (see Covariation (Correlation) Within an Assemblage), and understand how assemblages change over space and time (see Variation Between Assemblages Across Space (β diversity) and Variation in an Assemblage Over Time (Dynamics)). The study of assemblages has led the way in helping ecologists to understand the important influence of scale. And increasingly our understanding of assemblages is providing tools to help humans to measure and understand the consequences of human-caused global change.

Species Coexistence

Robert D Holt, University of Florida, Gainesville, FL, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Coexistence The state of two or more species being found in the same place at the same time.

Community The assemblage of species found in a defined area, in which these species can interact.

Competition The most widely used definition: use or defense of a resource by an individual that reduces resource availability to other individuals. Alternative definition: a reduction in one species' growth rate because of the effects of another species.

Food web The pattern of feeding relationships among organisms.

Lotka–Volterra competition model A model describing the per-capita growth rates of two competing species as linear, declining functions of the abundances of each species.

Mechanistic models of population dynamics Models that are explicit about resource consumption, the relationship of consumption with demography, and mortality factors.

Microcosm studies Laboratory experiments involving population dynamics of small organisms with short generation lengths.

Natural enemy Any species that consumes or parasitizes another species, a general term that includes predators, herbivores, parasites, pathogens, and parasitoids.

Niche (Grinnellian/Hutchinsonian) The range of resources and conditions within which populations of a species are expected to persist. (Eltonian): The role of a species in a community.

Open communities Communities that receive immigrants from external sources and may export emigrants as well.

Permanence A property of communities that ensures the long-term coexistence of species because community trajectories (variation in numbers through time) have no species approaching very low numbers.

Zero-growth isoclines In a graph with axes describing factors important to population growth (e.g., resource abundance), a line along which a population's growth rate is zero.

Introduction

The Oxford English Dictionary states that to “coexist” is “to live together in the same place, at the same time, with another.” The topic of “coexistence” focuses on how biological species are organized into communities, in space, and through time. Identifying the factors that influence coexistence is fundamental to understanding biodiversity. Important factors that influence coexistence include interspecific interactions, spatial and temporal scales, and historical contingencies. Insights into coexistence come from laboratory and field experiments, historical reconstructions and observational studies, and theoretical explorations. The topic of coexistence has had a long history in community ecology, some appreciation of which is necessary to understand contemporary perspectives. After a few general remarks about how scale, interactions, and the notion of permanence are related to coexistence, the author provides a survey of the “phenomenology” of coexistence and exclusion, and the lessons derived from field and classic lab studies. The author then discusses key ingredients in both historical and current theoretical interpretations of species coexistence, emphasizing conceptual generalities rather than model details, and concludes with suggestions regarding significant unanswered questions about coexistence.

General Issues

The Importance of Scale

In some sense, all the species in the teeming plenitude of life present on Earth coexist because they are found in one place

(Earth) at one time (now). However, from the perspective that matters most to an individual organism such as a vampire bat, a tulip, or a flatfish – the perspective defined by the space that an individual occupies or moves within over its life span – populations of any given species co-occur with only a tiny fraction of all living things. The same holds for community samples, for instance those gathered in the quadrats beloved of plant ecologists or the towed plankton nets of limnologists; the number of species recorded is always much fewer than the potential number. That is, what counts as “coexistence” varies with the scale of ecological inquiry. Viewed at small spatial scales, tailored to the ecology of individual organisms, or seen through the lenses of conventional field methods, most species in the global flora and fauna do not coexist. However, even at this scale, many (and sometimes very many) species can coexist. Species coexistence is also temporally bounded. In the long term, most species face extinction, and even in the short term, coexistence may be transient rather than permanent.

The Importance of Interactions

Species (like ships passing in the night) may either coexist or fail to do so for reasons having nothing to do with each other. A null model of community organization is that communities arise from the independent responses of species to the environment. However, coexistence often reflects interactions among species. Sometimes, species may interact in such a way that species identity, *per se*, does not really matter. In recent years, a neutral theory of community organization has been developed by scientists such as Steve Hubbell and Graham

Bell, which assumes that all individuals within broadly defined groups (e.g., trees competing for space in a tropical forest) have equal probabilities of giving birth, dying, and dispersing to new locales, irrespective of taxonomic identity. This assumption seems biologically implausible, yet the neutral theory performs surprisingly well in predicting many patterns in species-rich communities (Rosindell *et al.*, 2011). Neutrality does not predict perpetual coexistence, but instead transient coexistence as species drift in abundance, some increasing and others decreasing due to chance. In a closed neutral community, in the long run, just one species persists. Given immigration, species richness can be maintained if external source pools harbor multiple species. Yet at a sufficiently large scale, there can be no immigration, and maintenance of diversity in this theory ultimately requires recurrent speciation. The neutral theory is an important – and still controversial – contribution to community ecology, highlighting the importance of speciation, dispersal, and drift (chance changes in abundance) as potential influences on coexistence and species richness.

Close analyses of particular species, however, often show that one cannot understand distribution and abundance without considering species-specific traits and deterministic processes of interspecific interactions. In the rocky marine intertidal, for instance, over broad regions there are repeatable patterns of zonation, with different species predictably dominating at different tidal zones (e.g., barnacles high up in the splash zone, and mussels crowding the lower depths). Experimental species removals often lead to expansions in the width of the zone occupied by other species, demonstrating the importance of interspecific interactions. The remainder of this article will largely focus on these more deterministic processes that influence species coexistence.

Familiar categories of interactions include competition for resources, natural enemy–victim interactions (a “natural enemy” is any species that consumes a species of interest, such as in predator–prey and host–pathogen interactions), commensalisms and mutualisms (e.g., plant–pollinator relationships), direct mechanisms of interference such as allelopathy (in effect, poisoning), and a broad range of environmental modifications (collectively called “ecological engineering”). In the study of coexistence, competition has received by far the most attention, but there is increasing emphasis as well on how natural enemy–victim interactions and mutualisms influence coexistence. Interactions are not fixed properties of species, or of species pairs or larger ensembles, but can vary in strength and pattern as a function of the physical environment and many contingent details of community structure. If species A affects species B, and species B in turn influences species C, there is an indirect interaction between A and C. Sometimes, this indirect interaction reflects altered abundances. For instance, an effective predator may reduce an herbivore’s abundance, relaxing consumption on plants. Other cases are more subtle, involving shifts in species’ traits. For example, Os Schmitz has shown that the presence of a spider can lead to altered habitat use by grasshoppers, thereby altering grasshopper impacts on plant communities. A complete understanding of coexistence requires one to consider indirect and direct interactions among multiple species. Interspecific interactions may be strongly asymmetrical, and indeed,

interactions frequently cause species exclusion rather than coexistence. Analyzing mechanisms of coexistence and exclusion forms an essential part of the conceptual core of the discipline of community ecology.

Coexistence and Permanence

Coexistence emerges from the assembly of communities by colonization from species pools at larger spatial scales. The paleontological record shows that species’ distributions are not stable but move in concert with climate change, fluctuations in sea level, and the stately movement of the continents. Chance vicissitudes of dispersal provide a small trickle of potential colonists “testing the waters” outside their normal range, but some dispersal gaps may be near-impassable. Local coexistence at the very least requires species’ geographical ranges to overlap. The success of human-mediated introductions suggests that many species do not coexist together today naturally in local communities primarily because historical factors prevented them from ever encountering one another.

Within a species’ geographical range, for it to be a member of a local community, at one time it must have colonized, increasing from low numbers. Given the vagaries of climate and fluctuations in the abundance of other species, resident species also experience times of low abundance and extinction risk. To persist, a species must be able to rebound from these dangerous troughs of low numbers. A robust form of coexistence is for each species to be able to increase when rare. If all trajectories describing fluctuations in a community are bounded away from zero, all species in the community will coexist. This criterion for coexistence is called “permanence” in mathematical ecology. Examining conditions for increase when rare provides a natural protocol for both experimental studies and mathematical models of coexistence. Permanence is always relative to a certain spatial and temporal scale. A given pair of species may not coexist indefinitely in any single site but nonetheless coexist at larger scales across many sites, and in the neutral theory, all coexistence is impermanent.

Constraints on Coexistence: Examples from Introduced Species

In recent times, humans have greatly accelerated movements of species into novel habitats, both as deliberate introductions (e.g., most lowland birds found in Hawaii) and as incidental “hitchhikers” tracking human transport (e.g., many benthic invertebrates in San Francisco Bay are exotics released as byproducts of ship ballast dumps). The fates of introductions suggest that species interactions can constrain coexistence.

Competition

Classical biological control involves deliberately introducing species to control pests. Between 1947 and 1952, the Hawaii Agriculture Department released parasitoid species to control the oriental fruit fly, an economically significant pest. (Parasitoids are insects, e.g., braconid wasps, whose larvae live

within and ultimately kill their hosts, such as caterpillars.) Three wasps in the genus *Opius* were considered to be potential control agents. The first species established, *Opius longicaudatus*, parasitized approximately 20% of the fruit fly hosts. The second species introduced, *Opius vandenboschi*, was more effective, parasitizing about 30%; as *O. vandenboschi* increased, *Opius longicaudatus* decreased toward extinction. The third species, *Opius oophilus*, was even more effective, parasitizing up to 80% of the hosts and in turn replacing *O. vandenboschi*. This system provides an example of competitive exclusion in exploitative competition, where species dependent on a single limiting resource (here, host insects) cannot coexist. Increasing parasitism reduces the availability of unattacked hosts. The competitive dominant in this pattern of competitive displacement is the parasitoid species that persists at the lowest host abundance – an example of a simple rule of dominance in resource competition discussed below. Understanding how multiple species persist on a limited resource base is a perennial theme in the study of coexistence.

Natural Enemies

Very effective control agents can, after introduction, eliminate the target species (and thus themselves) over broad areas. The floating fern *Salvinia molesta* from Brazil escaped from a garden in Sri Lanka and became a serious aquatic pest in much of the Old World wet tropics. The beetle *Cyrtobagous salviniae* was introduced in Australia and proved highly successful at limiting the fern, which (with the beetle) is now found in only a few scattered populations. This example illustrates another species coexistence problem: how do effective natural enemies manage to coexist with their prey without overexploiting them and driving themselves to extinction?

Community and Spatial Contexts

Many game departments routinely introduce game species. Failed introductions reveal constraints on species coexistence. Caribou were once common in the Maritime Provinces but declined during the 1800s to extinction by 1915. Attempted reintroductions failed because the caribou pick up a nematode parasite (carried by snails and incidentally consumed as the caribou forage on vegetation). The nematode, lodging in the caribou brain, is fatal within a few months. The nematode population is sustained by another host, white-tailed deer, which tolerates parasitism. Deer are abundant because land practices by European settlers in the nineteenth century expanded second-growth habitats that deer favor; this may explain the disappearance of caribou. Caribou herds wander very widely, and so readily encounter nematode-laden snails. Another ungulate species, moose, coexists with deer, even though infected moose also quickly die. Moose and deer overlap in diet and can compete; in contrast, caribou and deer do not overlap in diet. Nonetheless, it is caribou, not moose, which have been indirectly excluded by deer. Moose are relatively sedentary (for their body size) and can occupy patches of highland forests with deep winter snows, where deer do not penetrate. At the coarse scale of North America, caribou and white-tailed deer coexist but with little spatial overlap among

their ranges. Moose and deer, in contrast, overlap geographically, coexisting at the level of landscapes, but at a finer scale, they show spatial segregation in habitat use.

This example illustrates several points. First, natural enemies can prevent coexistence. Second, coexistence or exclusion may arise from complex webs of multispecies interactions. The nematode directly causes exclusion of caribou, but viewed more expansively, exclusion is caused by the entire vegetation–snail–deer ensemble, which collectively governs nematode abundance and hence caribou infection rates. Third, movement patterns can influence interspecific interactions. Moose and white-tailed deer coexist at the landscape scale because moose have spatial refuges from infection, whereas caribou do not and are thus excluded.

Coexistence and Exclusion: Messages from Bottles

The previous examples strongly suggest the importance of species interactions in determining coexistence but are not conclusive. Without detailed observational studies tied to parameterized models or rigorous field experiments, it is difficult to persuade skeptics that other hypotheses are not also plausible. As an alternative, one simple but illuminating approach to the study of coexistence is to put together a few species in a confined setting and see what happens.

The study of “nature in a bottle” simplifies the world in important respects (e.g., such experiments typically focus on a few species in closed and temporally constant environments). For this reason, such experiments are viewed skeptically by some ecologists. Despite limitations, a wealth of important messages about species coexistence have emerged from bottle experiments – messages that have proven robust when applied to natural communities. Microcosm studies of ecological processes are now enjoying a renaissance in community ecology.

Competition Experiments

The term “competition” usually refers to an interaction among individuals (within or among species) that arises because they seek a resource in short supply. If this involves direct harm, the interaction is referred to as “interference competition.” If instead competition involves depletion of a resource, one refers to “exploitative competition.”

Protozoa

Most ecology textbooks (Hutchinson, 1978) recount famous experiments by the Russian ecologist G. F. Gause, who, as a young man in the 1930s, put mixed cultures of protozoa into vials to study species coexistence. Gause’s experiments compared populations of the ciliate protozoans *Paramecium aurelia* and *Paramecium caudatum* grown separately, and together, on a nutritive medium containing their essential resource (bacterial food). Both species thrived when alone, but *P. aurelia* usually displaced its congener in joint cultures within 30–50 generations. This outcome was reversed if the medium was completely replenished with fresh nutrient on a regular basis. Gause argued that metabolic byproducts were building up in the experiments, and that part of the dominance of *P. aurelia* involves

its resistance to the chemical byproducts of metabolic activity as well as its superior ability to exploit the food base. Here, competition combines both environmental modification by a species and exploitation of a limiting food resource.

In other experiments, Gause found that *P. aurelia* could coexist with another species, *Paramecium bursaria*, even in the confines of a closed culture. *P. bursaria* contains symbiotic algae, which release oxygen in photosynthesis. In incompletely mixed cultures, bacteria accumulate on the bottom, creating a zone slightly depleted of oxygen. The protozoan with the algae in effect carries its own oxygen supply into this hypoxic habitat and so can use a food source unavailable to the other, competitively superior species. Here, coexistence depends on both the availability of different habitats and differential species' abilities to utilize those habitats.

Beetles

Many ecologists have examined the dynamics of mixtures of beetle species competing for grain in containers. L.C. Birch examined several species combinations that fed on wheat or maize under different conditions of temperature and moisture. Usually, one species won. The criterion for dominance was simple: The winner always had the highest intrinsic growth rate (the maximal rate of population growth when a species is rare and growing alone). However, the identity of the winner depended on both the resource type and the physical conditions. Moreover, competitive exclusion sometimes required many generations; in one experiment, the apparent loser survived until the experiment had to be terminated.

Experiments by T. Park with a different set of stored grain pests (*Tribolium castaneum* and *Tribolium confusum*) revealed a different possibility – for some abiotic conditions, the outcome was indeterminate. Either species could win, with the winner tending to be the species initially most abundant. The net interaction between these beetles combines several mechanisms, including exploitation of a shared resource and cannibalism (both within and between species). In one experiment, Park intriguingly observed that when a coccidian parasite, *Adelina* sp., was present, the normal dominant *T. castaneum* became a weak competitor, permitting the persistence and even the dominance of *T. confusum*.

Sometimes, coexistence in microcosms reflects very subtle differences between species. Crombie raised two grain beetles (*Rhyzopertha dominica* and *Oryzaephilus surinamensis*) in vats of cracked wheat and found indefinite persistence, despite the fact that there seemed to be just a single resource. The main difference in the two species seemed to be in larval feeding habits; larvae of *Oryzaephilus* lived and fed outside the wheat grains, whereas larvae of *Rhyzopertha* were sufficiently small to live and feed from within the grains. This slight difference sufficed for the competitors to coexist.

Key Insights

Several insights emerged from “bottle” studies of competition. First, species competing in confined quarters in a homogeneous medium for a single limiting resource typically do not coexist. Second, the winner depends on the conditions, and the outcome depends on the environment – there is no universally superior competitor. Third, exclusion is not

instantaneous and may require many generations; this leads to the possibility of transient coexistence. Fourth, indefinite coexistence occurs but requires heterogeneity in the environment as well as differences in species' responses to this heterogeneity. However, species' differences permitting coexistence can be quite subtle. Fifth, pairs of species can interact in many distinct mechanistic ways (e.g., via impacts on resource levels or on levels of pollution from metabolic waste). It is difficult to generalize among studies if one has not clearly identified and characterized specific mechanisms of interaction. Finally, the outcome of competition can vary due to effects of other species, including parasites and mutualists.

Predation

In the classic literature, compared with studies of competition, less attention was paid to predator–prey and host–parasite interactions (and essentially none to mutualism). Gause did carry out experiments with the predatory protozoan *Didinium nasutum* and a prey protozoan *P. caudatum*. The predator quickly overexploited its prey and became extinct. To achieve coexistence, Gause concluded that there needed to be a spatial refuge for prey, inaccessible to the predator, or recurrent immigration. Luckinbill reexamined the unstable predator–prey pair studied by Gause but reduced the encounter rate between predators and prey by adding methyl cellulose (a thickener) to the medium so as to slow predator movement. Reducing movement rates in effect expands the size of the spatial arena of the interaction (scaled by the distance a predator moves per unit time). This led to stable coexistence. The qualitative message of microcosm experiments on predation is that patchiness, localized dispersal, and spatial heterogeneity (e.g., refuges) may facilitate the coexistence of effective specialist predators and their vulnerable prey.

Constraints on Coexistence: Rules of Dominance

The Competitive Exclusion Principle

The experimental observation that in homogeneous well-mixed lab environments it was difficult to achieve coexistence between similar species became enshrined in ecology as Gause's principle or the “competitive exclusion principle.” Another way to state this principle is to note that, to coexist indefinitely, different species must have distinct ecologies.

Assume we are examining a local community defined by a spatial scale in which all individuals can reach all sites over a single generation. The basic logic of the competitive exclusion principle is impeccable (Levin, 1970). Consider two species with continuous generations, where both species respond to the same environmental factors, denoted by E . The quantity E could be many things (e.g., resource availability, predator abundance, or the competitors' own summed numbers). We make three assumptions: (i) There is a single limiting factor, (ii) the species interact in a closed habitat (i.e., no immigration), and (iii) each species when alone settles down to an equilibrium with constant densities (i.e., the environment is temporally constant). The growth rate of species i is $dN_i/dt = N_i f_i(E)$, where N_i is its density. To complete the

model, one must also characterize the effect of the species themselves on the magnitude of E , leading to either direct or indirect density dependence in demographic parameters such as birth or death rates. For example, if two species are consuming a single resource, consumption depresses resource levels, reducing growth rates.

For species i , there will be some value of the environmental factor, E^* , at which that species equilibrates. It is a biological truism that any two species will almost surely differ in some way. Hence, it is very improbable that they will have exactly the same values for E^* . In other words, there should be no long-term persistence of two species limited by a single factor in a constant, closed environment

Exploitative Competition: The R^* Rule

What counts as a “limiting factor” needs to be interpreted quite broadly and can be difficult to identify in practice. Nonetheless, sometimes a single, simply characterized limiting factor defines a rule of species’ dominance. For instance, the Hawaiian parasitoids fit the “ R^* rule” proposed by David Tilman; that is, the dominant species, given exploitative competition for a single resource, is the species persisting at the lowest resource level. (The asterisk denotes equilibrium, and R^* is the resource level at which a given consumer species is in demographic equilibrium.) An advantage of this dominance rule is that one can measure R^* of each species when alone and then predict the outcome of competition. A species may have a low R^* and be competitively superior either because it is efficient at resource consumption or because it has low mortality (e.g., it can escape predation).

The R^* rule successfully predicts the outcome of competition among phytoplankton competing for single nutrients in microcosms and also characterizes competition in some natural systems. For example, in the nitrogen-poor soils of Cedar Creek, Minnesota, plant species compete for nitrogen. Wedin and Tilman showed that species with low R^* for nitrogen won in pairwise competition experiments. If species had similar values for R^* , the rate of competitive displacement was greatly reduced, as expected by theory.

Apparent Competition: The P^* Rule

Analogous “rules of thumb” arise in other situations. For instance, Sharon Lawler carried out a microcosm experiment in which a predatory protozoan (*Euplotes patella*) coexisted fine with either of two prey protozoans (*Tetrahymena pyriformis* and *Chilomonas paramecium*) grown alone. However, when all three species were placed together, *Chilomonas* was driven extinct. In single-prey cultures, *Tetrahymena* sustained four times the number of predators as did *Chilomonas*. In mixed cultures, the latter species suffered higher predation than it could sustain. The limiting factor here is the abundance of a shared predator, which responds numerically to its prey. Let P^* be the abundance of the predator sustained (and tolerated) by a prey species. A “ P^* rule” now describes dominance: The winning prey species is the one sustaining greater P^* . This form of indirect competition between species arising from shared natural enemies (including parasites) is called apparent competition (Holt and Lawton, 1994); the word “apparent” is used because the interaction has comparable consequences for coexistence as does classical exploitative competition for

resources but may occur even between species with totally different resource requirements. Dominance in apparent competition may reflect different vulnerabilities to a natural enemy (as in the caribou example) or because one prey is highly productive and sustains an abundant enemy population (as in Lawler’s experiment).

Mechanisms of Coexistence

The previous discussion emphasized constraints on species coexistence arising from interspecific interactions. Rules of dominance are important conceptual tools that quantify these constraints and help identify biological traits leading to dominance. However, even in simple microcosms, coexistence can occur, and most natural communities are rich in species. Species in principle may coexist when any of the assumptions leading to the competitive exclusion principle are violated. This suggests three classes of mechanisms promoting species coexistence of potentially competing species in a local community:

1. Species may coexist in a closed, temporally constant world if they experience different limiting factors; this includes classical niche partitioning of resources, as well as mechanisms involving predation and parasitism, and direct interference.
2. Species may coexist, even though they experience the same limiting factor, if the environment is temporally variable and species respond differently to this temporal variation (temporal niche partitioning).
3. Species may coexist if the environment is spatially open or interactions are localized; the implications of space for coexistence can include spatial niche partitioning at scales broader than the local community, mechanisms such as colonization–competition tradeoffs in metapopulations, and microscale habitat partitioning.

From the 1950s to the mid-1970s, stimulated largely by G.E. Hutchinson and his brilliant student Robert MacArthur, most community ecologists emphasized classical niche partitioning in studies of species coexistence. In recent years, the balance of attention has shifted markedly to a broader range of coexistence mechanisms. Ecologists now believe that maintenance of diversity – coexistence writ large – often depends on spatial dynamics in open communities, food web interactions (including predation and parasitism), and non-equilibrium dynamics reflecting either extrinsic temporal variation or the endogenous instability of complex ecological systems. Moreover, as noted above, some ecologists have concluded that in natural communities, many species co-occur, without necessarily permanently coexisting, in the sense of tending to increase when rare.

Traditional Approaches to Coexistence

Classical Niche Partitioning

Competitive exclusion is expected if the growth rates of multiple species are determined by a single limiting factor. Species may coexist, even in an unvarying and spatially confined bottle,

given multiple limiting factors, such that each species is limited more strongly by its own distinct set of factors. When species coexist, one sensible approach to begin to understand this coexistence is to map their niche requirements against the spectrum of limiting factors present in the environment. This basic methodology has been a source of significant insights for much of the history of ecology and continues to be fruitful. The classic paper in this genre is the 1958 study by Robert MacArthur of wood warblers in a New England boreal forest. Five warbler species in the genus *Dendroica* occurred in the same tract of forest; all had similar body sizes and ate the same range of insect taxa. MacArthur found that the species segregated with respect to microhabitat (with one species feeding at tree-top, another in low branches, and so on). He argued that because of this microhabitat partitioning, each species consumed an independent pool of insect prey, thereby reducing the potential for competitive exclusion. This study led to a proliferation of field studies of niche partitioning patterns.

Lotka–Volterra Competition Model

MacArthur's study was motivated in part by Gause's experiments on competitive exclusion, which in turn were stimulated by theoretical models of interacting species explored by the Italian mathematician Vito Volterra. In the usual textbook formulation (the famous Lotka–Volterra equations; see for e.g., Morin, 2011), the competitive effect of one species on another is expressed as a direct, density-dependent reduction in abundance:

$$\frac{dN_1}{dt} = r_1 N_1 (K_1 - N_1 - \alpha_{12} N_2) / K_2 \quad [1]$$

where N_1 and N_2 are the abundances of competing species 1 and 2, respectively, K_1 is the carrying capacity of species 1, r_1 is its intrinsic rate of increase, and α_{12} is a competition coefficient (the equation for species 2 is the same, with subscripts 1 and 2 switched). The quantity α_{12} measures the effect an individual of species 2 has on reducing the per capita growth rate of species 1 relative to the effect of an individual of 1 on its own species. Both species increase when rare and hence coexist if

$$\frac{1}{\alpha_{21}} > \frac{K_1}{K_2} > \alpha_{12}. \quad [2]$$

The outer inequalities imply $1 > \alpha_{12}\alpha_{21}$. This necessary condition for coexistence states that at least one competitor experiences stronger intraspecific than interspecific competition. If the inequalities are reversed, either species can exclude the other if it is initially sufficiently abundant (as in Park's experiments with *Tribolium*). With competition coefficients near unity (i.e., density dependence occurs uniformly within and between species), the species with higher carrying capacity wins.

The Lotka–Volterra model usefully describes competition, and multispecies extensions have been the focus of a rich body of theoretical work. However, the model is difficult to use predictively because its parameters must be measured during competition experiments. Moreover, taken literally, the model best describes competition due to direct interference.

Recognition of these limitations led to the development of a wide range of mechanistic models of resource–consumer and other interspecific interactions beginning in the late 1960s, and continuing to the present.

Whither Limiting Similarity?

This development was concordant with interest in the important concept of “limiting similarity,” which is the notion that there might be a quantifiable limit to how similar species can be in their utilization of resources and still coexist. To gain an understanding of the idea of limiting similarity, note that in expression 2, similar species should have competition coefficients near 1, and so coexistence will not occur unless carrying capacities are finely balanced. For a period in the history of the discipline, the goal of quantifying limiting similarity represented a “holy grail” for community ecology. Early theoretical explorations suggested that simple rules might permit predictions of the maximal number of species that could persist on a defined resource base, providing a basic tool for understanding biodiversity patterns. These studies were based on the Lotka–Volterra model coupled with assumptions about resource use. In some limiting cases, the Lotka–Volterra model emerges as a reasonable approximation of more complex resource–consumer interactions, and one can directly map niche overlap onto measures of competition. With simplifying assumptions about symmetry in resource use, environmental variation, and other factors, a limiting similarity of competing species could be calculated and compared against observed similarities. For instance, using MacArthur's warbler data, it was assumed that spatial overlap in foraging (measuring similarity) was directly related to competition coefficients. Substitution into the model showed that observed overlap was consistent with long-term coexistence. If measures of niche overlap in fact portray the strength of competition, observational studies of overlap and niche partitioning would provide a powerful link between descriptive analyses of community patterns and the dynamical forces of species interactions.

Further exploration has tempered the initial flush of enthusiasm for this approach to coexistence. After considerable grinding of mathematical gears, theoretical ecologists have concluded that limiting similarity is not likely given by a single number that pertains across all systems. Instead of a single general theory of limiting similarity and coexistence, there are many special theories. Moreover, there is a real sense in which increasing species similarity facilitates, rather than hampers, coexistence. Equation [2] describes bounds on the permissible differences in the two species' carrying capacities. If the α_{ij} are less than unity, coexistence is more likely if carrying capacities are nearly equal rather than very different. The more similar species are in their demographic responses to the environment (i.e., their basic fitness), the more similar their carrying capacities are likely to be. All else being equal, this kind of similarity promotes coexistence.

Manipulative Field Experiments

Recognizing the limitation of observational studies of niche partitioning as evidence for competition, ecologists turned to manipulative field experiments, removing species

and monitoring changes in the abundance of others. Reviews of such experiments show that when species are suspected to compete (e.g., because of overlap in resource requirements and habitat), they often do compete. For instance, Hairston noted that in the Great Smoky Mountains, two species of *Plethodon* salamanders had altitudinal ranges that were nearly mutually exclusive, with only a narrow range of overlap. In contrast, in the Balsam Mountains, altitudinal overlap was extensive. Hairston hypothesized that this was due to stronger competition in the Smokies, and using reciprocal transplants and removals, he demonstrated that competition (due to aggression) was indeed much stronger in the narrow overlap zone in the Smokies.

Unfortunately, few field experiments have been directly tied to mechanistic models of competition. Moreover, such experiments tend to focus on species that already coexist, at least to a degree; removals then assess the magnitude of competition, given coexistence, rather than coexistence or exclusion *per se*. One study that directly addressed coexistence was performed by Bengtsson, who studied three species in the zooplankton genus *Daphnia* (which compete exploitatively for algal food) on the coast of the Baltic Sea. Observational studies suggested that usually just one, or more infrequently two, species was present in any given pool. Bengtsson added all possible combinations of the three species to artificial pools and found that there were no extinctions in the single-species pools. Yet high extinction rates occurred in the two- and three-species sets. This study directly demonstrates the importance of competition in constraining coexistence in natural conditions.

Mechanisms for Local Coexistence: Current Approaches

Mechanistic Models of Multiple Limiting Factors

Most theoretical studies of competition today focus on models in which the mechanisms of interaction are clearly described. Detailed analyses of mechanistic models of competition are often mathematically challenging, but important insights

can often be gleaned from simple graphical analyses. A generalization of the competitive exclusion principle is that “coexistence of n species requires n limiting factors, and n distinct feedback effects via the environment.” Mathematically, one expresses the growth rate of each species as a function of a vector of limiting factors (e.g., $dN_i/dt = N_i f_i(E_1, E_2, \dots)$), and adds equations for the environmental factors themselves, which in turn depend on N_i . For instance, an environmental factor might be resource availability, which becomes reduced by consumption. For illustrative purposes, the author discusses one example in detail (MacArthur 1972, cited in Chase and Leibold 2003, which also treats many other cases).

Consider two species competing for two resources. Assume that exploitation depresses resources and that resource-consumer dynamics tend toward a stable equilibrium. For each species, there will be some resource combination that allows equilibrium (with births matching deaths). On a graph with axes of resource abundance, assume that this combination is a straight line, as in the line marked 1 in Figure 1(a) (for species 1) (MacArthur, 1972). This line is the “zero growth isocline” of species 1. The linear form of the isocline implies that resources are qualitatively substitutable so that a sufficient supply of one compensates for low abundances in the other. At equilibrium, resource abundances lie along this line; if resources lie above this line, species 1 should increase, depressing resource levels (with reverse dynamics below the line). Equilibrial coexistence requires that resource levels be such that both consumers have zero growth; graphically, the isoclines must cross. The isoclines do not intersect (Figure 1(a)) if species 1 has a lower R^* for each resource. If species 1 is resident and at equilibrium, and a few individuals of species 2 are introduced, the introduction will fail due to competitive exclusion. If isoclines cross (Figure 1(b)), species 1 has a lower R^* for one resource than does species 2, and the converse is true for the other resource. Coexistence is now possible.

Crossing isoclines reflect differences in species’ ecologies and the existence of distinct limiting factors (here, linear combinations of resources). However, such niche differences do not suffice for coexistence. As in the Lotka-Volterra model, there must be broad similarities in how the two species

Figure 1 Graphical model of resource competition. The isocline of species i ($i=1,2$) is a combination of resource abundances where it has zero growth. At lower resources (toward the origin), a species declines, (a) Competitive exclusion of species 2 by species 1; (b) Potential coexistence. (See text for details.)

respond to the environment. In **Figure 1(a)**, exclusion occurs because the species are too different in their overall resource requirements. Coexistence, in contrast, is possible if overall resource requirements are approximately the same for the two species (**Figure 1(b)**). Peter Chesson has suggested that one can broadly understand the requirements for coexistence in terms of the interplay of “stabilizing mechanisms” arising from different kinds of niche differentiation, and “equalizing mechanisms”, which means that no species has too great a basic fitness advantage.

Having crossing isoclines does not guarantee coexistence. If species 1 is alone, and resources equilibrate at point a (in **Figure 1(b)**), species 2 invades. However, if resources instead equilibrate at point b, species 2 is excluded. If species 2 is resident, species 1 invades if resources are at point c but not at point d. Comparing these points to each species' R^* (for each resource) suggests a necessary requirement for coexistence: Given two resources, each competitor must have the greater impact on that resource for which it has the lower R^* . In effect, each species must limit itself (via resource depletion) more strongly than it limits the other species. Whether or not this occurs depends on both the intrinsic renewal rates of the resources and the rates of resource consumption. A complete analysis of conditions for coexistence requires one to track the dynamics of both consumers and each resource, and goes beyond the scope of graphical models. But this graphical model illustrates the important insight that coexistence depends on a balancing of overall similarities and differences in species' niche requirements. It does not suffice for understanding competitive coexistence, because one must also consider feedback effects mediated through the species' impacts on their environments. This depends not just on species' properties, but the structure of the entire system in which the interaction is embedded, including ecosystem processes (e.g., resource renewal rates).

Food Web Effects on Coexistence

This general approach can be extended in many ways, for instance by including interactions among species across trophic levels. With predation, herbivory, or parasitism inflicted on competing species, one greatly increases the number of potential limiting factors. This is a large and complex topic, and the author briefly discusses some highlights here.

Specialist predators and parasites typically reduce the abundance of their favored species, freeing up resources for other nontarget species. This can facilitate coexistence if dominant competitors tend to attract more specialist predators or parasites than do subordinates. In tropical forests, specialist herbivores and pathogens sustained by adult trees can hamper recruitment by juveniles of the same species, freeing up resources that can be used by other species – an explanation of high tropical tree diversity called the Janzen–Connell effect. Generalist predators can have the same effect via fixed preferences for dominant competitors or if they reduce attacks on whichever species is temporarily rarest. Pathogens can likewise promote coexistence if their impacts are strongest on dominant competitors. For instance, at Silwood Park in the United Kingdom, an experimental

manipulation of foliar fungal pathogens using fungicide showed that competitively dominant grasses were reduced by parasitism, freeing resources for other species and thus enhancing diversity.

However, predators or pathogens that attack multiple species can hamper coexistence (as discussed previously). This is particularly likely if the prey species under attack do not strongly compete, and if some prey species are sufficiently productive to sustain high abundances of the predator or parasite (Holt and Lawton, 1994). Coexistence can occur, despite apparent competition under high predation intensity, if different species utilize different refuges from predation – a subtle form of niche partitioning. In general, whenever species interact via multiple mechanisms (providing different limiting factors; e.g., different specialist pathogens on different tree species), coexistence may occur. As another example, if two species compete for a single limiting resource, the species with higher R^* may nevertheless persist if it can also consume the superior competitor. This mixture of predation and competition, called intraguild predation, is particularly common in aquatic food webs, and at higher levels in terrestrial food webs.

Local Habitat Heterogeneity

Traditional ecological models of interacting species such as eqn [1] assume that populations are spatially well mixed and average over local environmental variation. Relaxing this assumption often promotes coexistence, and for several distinct reasons. As shown in Gause's experiments, even in the confines of a microcosm, there can be spatial heterogeneity in abiotic conditions or resource availability that influences coexistence. Assume that within the microcosm each species has a set of conditions in which it is superior. If competitive interactions are sufficiently localized (e.g., because of limited movement or habitat selection), and each species spends more time in the microhabitat where it is superior, one can readily generate coexistence. This simple mechanism for coexistence via local habitat partitioning is very important. A review by Schoener (1974) of resource partitioning studies following in the footsteps of MacArthur's warbler study revealed the ubiquity of habitat differences among potential competitors; subsequent years have not altered this basic message. In animals, habitat selection can be an important mechanism promoting coexistence with local spatial heterogeneity. If individuals of a species (when rare) can discriminate among local microhabitats and spend more time in those that provide the greatest fitness rewards, the rate of increase at low N will be increased, relative to that of a species that utilizes habitats at random. If each species has a habitat in which it is competitively dominant, habitat selection will sharpen habitat partitioning and make coexistence more likely. Habitat selection can permit subordinate species to withstand superior competitors. Recent studies in east Africa suggest that the fleetness of the cheetah helps it persist in the face of direct aggression by lions and hyenas (who kill cheetah cubs) by allowing it to seek out areas with low lion and hyena densities. For many organisms (particularly terrestrial plants), an individual occupies a small site and interacts with only a few

neighbors during its lifetime. Probabilistic events of individual life histories (birth, death, and dispersal) lead to spatial variance in competition, even among sites with homogeneous physical conditions. Moreover, dispersal typically occurs over small spatial scales. Combining these two general facts together in models leads to nonuniform spatial patterns in which competition is typically stronger within species (because they tend to occur in clumps) than between species (which tend to become segregated spatially). This mechanism may help explain the coexistence of large numbers of similar coexisting species in many plant communities.

Temporal Niche Partitioning

Outside the controlled confines of the lab, environments are rarely constant. Temporal variation occurs on scales ranging from diurnal cycles to climatic changes over millennia. Many ecologists have intuitively felt that temporal variability should weaken negative interspecific interactions and facilitate coexistence. Theoretical studies (Chesson, 2000) have conclusively shown that this is not the case. Instead, temporal variation can provide a rich arena for differentiation among species in responses to the environments, which can promote coexistence. The basic idea is that if species A does better when the local environment is in state A' and species B does better when the local environment is in state B' , and the environment alternates between A' and B' , coexistence is possible. This can happen in several different ways.

Nonlinear Consumption

Assume two consumer species exploit a single resource and have saturating, nonlinear relationships between feeding rates and resource availability. Species A has a higher rate at low resource levels, whereas species B enjoys a higher feeding rate at high levels. In a constant environment, the resource level will equilibrate at a constant level, and the species with lower R^* wins. However, given large-scale seasonal variations in resource supply rates or mortality, resource levels may fluctuate between high and low levels, permitting competitive coexistence. This mechanism hinges crucially on nonlinearity in species' responses to the shared limiting factor; if feeding rate were to increase linearly with resource availability in both species, then even in a variable environment one would observe competitive exclusion. Studies of phytoplankton by Jef Huisman have shown that given comparable nonlinear consumption rates, competition for multiple essential resources can lead to unstable dynamics, even in constant environments, and this instability in turn permits coexistence of multiple species on just a few abiotic resources.

The Storage Effect

Desert rains fall sporadically and at different times in different years, sometimes early in the spring when the air is cool and at other times later in the hot summer. After rain, plant species emerge from the seed bank and compete for the pulse of water and soil nutrients. These annual plants are short-lived as adults, often completing their entire aboveground life cycle in

just a few weeks. Some species do disproportionately better following warm rains, whereas others do better following cold rains. The seeds each species produces enter the seed bank and germinate gradually during the following years (like a time-release capsule of past recruitment). This "storage" of good years of recruitment in a long-lived seed bank can facilitate coexistence. Again, it is not variability alone that allows coexistence, but variability combined with niche partitioning (different species being superior at different times) and the buffering effect of a long-lived seed bank, generating nonlinear responses of species to competition and the environment (Chesson, 2000). The storage effect exemplifies the growing recognition that the internal structure of populations (age, size, the presence of a seed bank, etc.) can have significant consequences for species coexistence.

Coexistence in Open Communities

In contrast to laboratory microcosms, many natural communities are open, coupled to the external environment via dispersal. Such coupling influences the local coexistence of species in many distinct ways.

Autecology and Population Size Effects

A consumer species that relies on a sparse or a sporadic resource, or extracts different essential resources in different habitats, may need to be mobile to persist. Or if absolute population size is small, extinction is risked even in favorable environments. Specialist consumers are likely to become extinct if their resources are rare. All these problems are aggravated, given barriers to dispersal and a small habitable area. These considerations may help explain why food chains are often short and specialist consumers absent on oceanic islands or isolated habitat patches. Moreover, as one increases the number of species coexisting deterministically on a fixed resource base, the abundance per species declines. Small population sizes have an increased risk of extinction; this can put a loose limit on coexistence, aggravated in small and isolated habitat patches.

Colonization–Extinction Dynamics

It was previously mentioned that strong specialist predator–prey interactions are prone to local extinctions. Coexistence may require dispersal among habitats, with prey dispersing sufficiently fast that they can find and reproduce within empty habitat patches before being discovered by predators. Similarly, if a guild of competitors utilizes a single resource, species with successively lower values of R^* should eventually colonize and displace species with higher R^* . If there are extinctions, asynchronous among patches, inferior competitors may have a temporary window of opportunity during which they can occupy habitat patches and reproduce sufficiently to colonize other patches. This metapopulation mechanism for coexistence is promoted by a tradeoff between competitive ability and colonization ability, and in principle, it can permit the coexistence of many competing species

(Tilman and Lehmann as cited in Tilman and Kareiva, 1997). Even if the inferior competitor is not a superior colonizer, it may be able to persist if it has a lower basal extinction rate when it occurs in patches alone compared with that of the superior competitor.

Landscape Heterogeneity

Coexistence Due to Spillover

If a species can persist in one local community, then with emigration, it can also be found in other nearby communities where otherwise it would be excluded. To model this “spillover” effect, assume that the species when rare declines at rate $r < 0$ because of competitive exclusion but immigrates from an external source at rate I . Its local dynamics are described by $dN/dt = I + rN$, which implies $N^* = I/|r|$ at equilibrium. A species that should be absent, considering only local interactions, may not just persist but even be abundant if there is a large rate of immigration (e.g., from a productive source habitat into an unproductive habitat), and the rate of exclusion is slow. In this scenario, the answer to the species coexistence problem ultimately requires analyzing population dynamics at the appropriate spatial scale, larger than the local community; spatial niche partitioning at this larger scale is responsible for coexistence.

Landscape Mechanisms of Exclusion

Spatial coupling can also generate novel mechanisms for exclusion. For instance, a species that is a superior competitor in one habitat may be excluded by a species that is inferior there but sufficiently abundant elsewhere so that via dispersal it can “swamp” the local habitat. For instance, Ted Case and associates recently described impacts of an invasive ant species, the Argentine ant, on an entire community of ants in coastal southern California. In contrast to many ants, the Argentine ant shows little intercolonial hostility and so has a high carrying capacity; it competes exploitatively for food but also preys on the juvenile life stages of some ant species. The Argentine ant readily becomes established in disturbed habitats. It can then spread into fragments of natural habitat resulting from intense development. Case suggests that in these fragments, many other ant species have declined to the point of extinction because of the sheer force of numbers. These effects are particularly dramatic in small fragments, and at the edges of large fragments, because of incursions from surrounding human-disturbed habitats in which the Argentine ant is abundant.

The author now returns to the studies of competition in bottle experiments and introduced species discussed previously (see Constraints on Coexistence: Examples from Introduced Species and Coexistence and Exclusion: Messages from Bottles). In light of what we now know about mechanisms of coexistence, it is easy to see why competitive exclusion was often observed in the classic bottle experiments with protists and grain beetles. The design of these experiments included most of the elements assumed in the syllogism leading to the competitive exclusion principle. The lab environments were climatically controlled, and the culture bottles were spatially closed, precluding two of the major classes of coexistence

mechanisms. The culture media and conditions (e.g., stirring) were set up to have a restricted number of limiting resources (ideally, one) and little within-culture spatial heterogeneity in limiting food resources; the communities are very simple, and so there is little opportunity for complex food web interactions. The most interesting result of these experiments may be that coexistence is observed at all. In the field study of introduced parasitoids, these species were specialized to the same host species, and the environment was relatively constant in time and homogeneous in space (the lowlands of tropical islands such as Hawaii have very stable climates, and the habitat is a deliberately homogenized landscape – plantations with regularly spaced fruit trees). It is likely that competitive exclusion is most readily observed in simple communities with few species in unstructured environments (e.g., islands tend to be low in species richness, particularly in heavily disturbed habitats dominated by introduced species). Most natural systems, in contrast, are temporally variable and spatially heterogeneous and harbor rich, complex communities with a multiplicity of interactions percolating through food webs; therefore, it should not be surprising that it is often difficult to document competitive exclusion in the wild. Recent analyses of time series of abundance and demographic rates in multispecies communities suggest that multiple regulatory factors are involved in species coexistence.

Future Directions

There are many important themes relevant to species coexistence that have not been addressed in-depth by ecologists but are likely to receive considerable attention in the near future.

Transient Coexistence

Ecological theory has traditionally emphasized equilibrium community states and the development of criteria for exclusion and indefinite persistence. However, exclusion takes place over some timescale. If this is long (e.g., relative to climate change), communities may exhibit transient dynamics and be far from equilibrium. This is particularly likely when considering interactions among species that are very similar in their niche requirements and environmental effects; as noted above, the abundances of similar species can vary through time in an essentially random fashion (i.e., Hubbell’s community “drift”). If drift is occurring, after a sudden shift in relative abundances, species should tend to stay where they are put, rather than return to their initial abundances. An experiment conducted by Mark McPeck and Adam Siepelski with damselflies showed that species gained no demographic advantage when perturbed to low numbers, consistent with the hypothesis that the species are co-occurring at present, but not necessarily permanently coexisting. An important task for future ecological theory and empirical work is to derive a deeper understanding of transient dynamics and the drift hypothesis as explanations for community structure, complementing views based on deterministic mechanisms of coexistence.

Allee Effects, Niche Construction, and Coexistence

Most ecological theory applies literally only to clonal, asexual organisms. However, most species of concern to ecologists are sexual. At very low population sizes, outcrossed sexual species should have depressed growth rates simply because the two sexes have to get together to reproduce – an “Allee” effect (positive density dependence in growth rates at low densities). Allee effects can influence coexistence. For instance, consider two sexual species with identical ecologies in a landscape with many habitat patches. If colonization is infrequent, whichever species arrives first in a patch should be able to dominate there because the first colonist increases until births just match deaths. When the second species appears, its potential birth rate will then also just match its death rate (because its ecology is the same as that of the resident), but its realized birth rate will be depressed because it has difficulties in pair formation at low numbers. Hence, in this patch, the second species to arrive will be excluded. In the landscape as a whole, the two species may coexist if by chance each species is the first to occupy a subset of patches. In some patches, both species may by chance appear initially in sufficient numbers so as not to experience the Allee effect; in these patches, abundances should drift through time. Over the entire landscape, patterns in abundance will not be correlated with any discernible factors in the external environment. The magnitude of the Allee effect varies greatly among species, depending on details of the mating system and mate-finding strategies (e.g., selfing in plants should greatly weaken Allee effects). This influence of mating ecology on coexistence may provide an as yet poorly understood source of variation among taxa in community structure. Allee effects can also arise when organisms modify their local environments so as to enhance fitness, as when a nitrogen-fixing plant enriches the soil environment, thereby easing seedling establishment. Theoretical studies suggest that such niche construction can at times hamper coexistence and at times facilitate coexistence.

Speciation Mode and Coexistence

Over long timescales, all species originate from other species. Understanding the mode of speciation may provide an insight into coexistence. For instance, sympatric speciation occurs when a lineage diverges within a single community. Most models of sympatric speciation depend on substantial ecological differentiation being present from the beginning; as speciation unfolds, the ecological differences between the two emerging species must be sufficient to withstand cross-mating. In other words, with this mode of speciation, mechanisms of coexistence (e.g., substantial habitat or resource segregation) are built into the very branching pattern of the phylogenetic tree. In contrast, allopatric speciation requires geographical isolation. This can occur without any ecological difference arising between the daughter lineages (although speciation should occur more rapidly if correlated with ecological divergence). Dispersal can later bring the daughter species together, with essentially any degree of ecological difference being possible at this stage. Speciation may also often involve changes in sexual selection and mating systems, which can occur with no change in ecological requirements. After

speciation, when these species’ ranges begin to overlap, relative abundances should be particularly prone to community drift.

Evolutionary perspectives, such as phylogenetics (understanding the family tree of life), are more generally transforming studies of coexistence. Darwin in *On the Origin of Species* hypothesized that competition should be particularly strong between closely related species, which are likely to have quite similar resource requirements. A recent laboratory study by Lin Jiang built on Gause’s classic experiments to examine this hypothesis. Pairwise contests among all possible pairwise combinations of 10 species of protists, combined with a phylogeny, revealed that the more closely related two protist species were, the more likely one would observe competitive exclusion, rather than coexistence, and if there was coexistence, the more likely one of the two species would be reduced greatly in its abundance. Recent studies show that the Janzen–Connell effect likewise has a phylogenetic signal, in that closely related tropical tree species inhibit each other’s recruits more strongly than do distantly related species, via shared pathogens – an instance of apparent competition among close relatives. Distantly related species have different defensive strategies, minimizing apparent competition and in effect providing an axis for niche differentiation.

Conclusions

In conclusion, understanding the factors that promote or constrain the coexistence of species is an ongoing enterprise at the intellectual core of the study of biodiversity. Community ecologists have a rich smorgasbord of hypotheses to explain both species coexistence and exclusion. In most natural communities, it is likely that many mechanisms operate simultaneously. A challenging problem is to ascertain the relative contribution of these ecological mechanisms of coexistence to explain major patterns in biodiversity in space and time. There is much work to be done in analyzing mechanisms of coexistence in the context of food web dynamics and metapopulations. Moreover, little mention was made in this article about commensalism, mutualism, and nontrophic interactions, all of which can be crucial to coexistence. An improved understanding of the factors governing species coexistence is needed to address many applied problems, particularly the conservation of natural communities. Given the importance of spatial openness for coexistence, the anthropogenic alteration and simplification of landscapes pose particular dangers to the continued coexistence of many species. Indeed, the basic unstated problem of conservation is how to structure our activities and modify our impacts so that most of the world’s biota can manage to coexist (at some spatial scale and, it is hoped, over long timescales) with just a single species, namely, ourselves.

Glossary

Community The collection of all species that occur together in space and time.

Intrinsic rate of growth A parameter, often designated as the variable r , reflecting the rate of change in population size due to births and deaths when resources are not limiting.

Population A collection of individuals of the same species in a defined geographic area that interbreed.

Population dynamics The change in the number of individuals in a population over time.

Resource Any necessity that is used or consumed for organismal growth, reproduction, or survival, including food, space, shelter, and nutrients.

Species A group of individuals that is capable of interbreeding; a species is composed of one or more populations.

Trait A quality possessed by an individual organism that affects its ability to survive and reproduce.

Introduction

The world can be divided into two parts – the living and the nonliving. Scientists refer to the nonliving component of the earth as the abiotic environment, and all living organisms are labeled biotic. Organisms survive and reproduce under many abiotic and biotic influences. Abiotic nutrients and elements are needed for survival and reproduction, and nutrient limitation is a common factor regulating limits to growth. Biotic factors also influence how an organism lives and grows. When organisms come into contact, they can facilitate, control, harm, use, or even help to propagate each other. Biotic associations that involve members of two or more different species are called species interactions.

Because the world contains a tremendous diversity of species, interactions among the biota are common. Many of these interactions are conspicuous and have a strong influence on the organization of biological communities. Studies of species interactions have produced a large body of data in a great variety of ecosystems, and these studies comprise an entire discipline called community ecology. The treatment of species interactions given here will briefly discuss the types of interactions found in nature and the simple mathematical representations of their effects, discuss the role evolution plays in shaping interactions, and provide some empirical examples. Because an increasing number of community ecologists are examining the effect of human influences on species interactions, the intersection of community ecology and conservation biology is also briefly discussed.

Pairwise Interactions

Species interact in a tremendous variety of ways, and associations can involve two, several, or many species. First, the various kinds of interactions that include only two species are discussed. (A discussion of multiple species interactions is provided in the section Multispecies Interactions.) When individuals of two species interact, this association is called a pairwise interaction. Pairwise interactions, like all interactions, are described by the direction and the strength of their effects. Direction refers to whether the impact on each associating organism is positive or negative, and interaction types are classified according to the direction of their effect (Table 1). Interaction strength refers to how much an interaction controls species' dynamics.

More specifically, the strength of an interaction is a measure of how much one species affects the population size and growth rate of another species. Strength is often detected as the effect on the population of one species by removing the second species. Imagine two interacting species, species A and B. If we would like to test the effect of B on A, we could remove B and measure the resulting change in population size of A. If species A responds to the removal of species B with a large change (increase or decrease) in abundance or population growth rate, we say that B has a strong effect on A. If little effect on the population of species A is seen by removing species B, the interaction plays a small role in the population dynamics of species A, and the influence of B on A is weak. In turn, the effect of A on B can be tested by removing A and observing how the population size or growth rate of B responds.

Table 1 Pairwise interaction types

Direction of effect on species 1	Direction of effect on species 3		
	+	–	None
+	Mutualism	Predation/parasitism	Commensalism
–	Predation/parasitism	Competition	Amensalism
None	Commensalism	Amensalism	–

Many factors determine how strongly two species interact. For example, the population size of either species, the behavior and age of the interacting individuals, the abundance and availability of abiotic resources, and the patchy nature of the environment all influence how strongly two species affect one another. In other words, understanding the nature of an interaction is more complicated than simply identifying that two species come into contact. In fact, even a simple experiment of interaction strength such as that described in the previous paragraph may not provide enough information on exactly how organisms interact with one another in different settings or circumstances. For example, the strength of an interaction can change at different times through the seasons or in different places in the species' habitat. The strength of pairwise interactions can also change due to the forces of evolution, but first the types and effects of pairwise interactions in ecological time are discussed.

Competition

Competition is characterized by the common use of resources by two or more species, and the effect of competition on all participating species is negative (Table 1). Members of the same or different species can compete for resources. Within-species competition is known as intraspecific, and between-species competition is called interspecific. Of these, interspecific competition meets the definition of a species interaction, and intraspecific competition will not be discussed.

Interspecific competition can be further divided into two categories: interference and exploitative. Interference competition is the more direct form of competition, in which individuals of one species actively dominate a resource, preventing or decreasing the access of another species to those resources. Exploitative competition, however, is less combative. It is the diminishment of a limited resource by a species so that the other species is not able to utilize as much of the resource as it would in the absence of the exploitative competitor.

We can predict how the population dynamics of two competing species will be affected by their interaction with the use of a mathematical model. A mathematical theory of competition began with the work of Lotka and Volterra in the late 1920s and early 1930s. The Lotka-Volterra model quantifies the influence of competition by expressing the population dynamics of each species in an equation that includes both growth in the absence of competition and the influence of competition itself. In other words, Lotka-Volterra represents the change in population size through time as a function of the growth rate of each species and the detrimental effect of competition on each population. Remember that the presence of competitors causes harm. This harm reduces the total number of individuals in each population that would be possible in the absence of competitors.

In the Lotka-Volterra model, two equations are needed to represent the population dynamics of competition (one equation for each species). The pair of equations describes the rate of change in population size with time for the two species. Subscripts represent a variable's species designation; hence, N_1 refers to the population size of species 1, and N_2 refers to the

population size of species 2. The relative effect of each species on the population size of the other is determined by the value of the competition parameter α . This competition parameter can also be interpreted as the amount of overlap between the two species in the resources they require.

The effect of one member of species 2 on one member of species 1 is represented by the parameter α_{12} , and the effect of species 1 on species 2 is the value α_{21} . The values of α_{12} and α_{21} can range from 0 to 1. If they take on a value close to 1, then the effect of one species on the other is very strong. If they take on a value close to 0, then the effect of one species on the other is weak. The values of α_{12} and α_{21} can be different from each other because it is not necessary that the two species affect each other equally. If the values of α_{12} and α_{21} are the same, this special case is called symmetric competition.

If both α_{12} and α_{21} are zero, then the two species do not compete at all and grow according to a simple expression known as logistic growth. In logistic growth, a population grows from zero to some carrying capacity, K , according to an intrinsic growth parameter, r , as shown in Figure 1. The hallmark of logistic growth is its density dependence. In density-dependent growth, the expansion of a population slows as the number of individuals in the population approaches the carrying capacity or the maximum number of individuals that a habitat can support. All of the terms in the following equation for species 1, except the component $\alpha_{12}N_2$, represent the logistic growth of species 1. The remaining $\alpha_{12}N_2$ term reflects the slowing or reduction in population growth of species 1 that results from competition with species 2. The same is true for the equation of species 2; the term $\alpha_{12}N_1$ represents the negative effect of competition with species 1

$$\begin{aligned}\text{Species 1 : } \frac{dN_1}{dt} &= \frac{r_1 N_1 (K_1 - N_1 - \alpha_{12} N_2)}{K_1} \\ \text{Species 2 : } \frac{dN_2}{dt} &= \frac{r_2 N_2 (K_2 - N_2 - \alpha_{21} N_1)}{K_2}\end{aligned}$$

on population 2's otherwise logistic growth.

Figure 1 Sample plot of logistic growth. N is the number of individuals in a population of a single species, and t is time. In logistic growth, the number of individuals increase quickly when the population size is small, but the rate of growth decreases to zero as N approaches the carrying capacity. Here, the carrying capacity is 2000 individuals.

These equations can predict the impact on N_1 and N_2 for different values of r_1 , K_1 , α_{12} , r_2 , K_2 , and α_{21} . For some values of r , K , and α , one species will drive the other to extinction. In other cases, however, each species can maintain a positive population size in the presence of the other ($N_1 > 0$ and $N_2 > 0$). One such case is shown in Figure 2, in which the population size of both species is plotted against time. To produce this graph, one begins with population sizes just larger than zero for both species and uses the competition equations to predict the change in population sizes (N_1 and N_2) as time passes. Note that in Figure 2, both species eventually reach a stable and constant population size.

What conditions produce an outcome in which two competing species can coexist? It can be shown that coexistence depends on the relative value of the carrying capacities of the two species in comparison to the values of the competition coefficients, α . In short, coexistence is possible whenever the value of the competition coefficients is less than the ratio of the carrying capacities (if $\alpha_{12} < K_1/K_2$ and $\alpha_{21} < K_2/K_1$). This makes intuitive sense: Two species are able to persist on the same resource if they have a relatively small effect on one another. In other words, there is a constraint on the amount of resource overlap (α_{12} and α_{21}) between two competing species that is given by ratios of their carrying capacities.

The idea that two species, based on the Lotka-Volterra equations, cannot significantly overlap in resource use is known as the competitive exclusion principle. Generally stated, no two species can occupy the same niche. (A niche can be imprecisely defined as a species' role in a community or the entire set of resources that a species requires.) If the same

Figure 2 Sample plot of the population growth of two competing species according to the Lotka-Volterra competition equations. N is the number of individuals; $N(1)$ refers to the number of individuals in one species, and $N(2)$ refers to the number of individuals in the other species. In this diagram, species 1 and species 2 coexist because the abundance of both populations is positive through time. The growth of each population appears logistic (see Figure 1), but because of competition, the level at which each curve stabilizes is less than the carrying capacity for each species. In other words, the number of individuals in a population in a competitive environment is smaller than the total number of individuals that is possible in the absence of a competitor.

niche was filled by two species, or if two species used exactly the same resources, the species would compete strongly, their α values would approach 1, and one of the two would be driven to extinction.

Additional factors not captured in the Lotka-Volterra equations influence coexistence, however, and species may coexist in situations in which classical theory would predict otherwise. The role that these factors play in coexistence reduces the general applicability of the competitive exclusion principle, and a number of more sophisticated competition models include these factors for specific situations. For example, spatial and temporal heterogeneity and variability of resources may enable a greater diversity of species to persist in an area than simple theory would predict (e.g., see Powell and Richerson, 1985; Tilman, 1994). In other words, the patchy nature of resources in a habitat may enable two species to reduce their overall competitive overlap. Alternatively, species may compete only when resources are in short supply.

Controversy regarding the role of competition in natural communities has resulted in a tumultuous debate in the ecological literature. Some authors argue that competition is a critically important factor regulating community composition. Others contend that competition is overemphasized at the expense of other types of interactions that are equally (if not more) important in determining the number and kinds of species that can persist in a community. This debate as to the importance of competition in controlling community structure is ongoing, but there is little argument that competitive interactions can be found and quantified.

Gause was the first to study competition in 1934 using experiments with two *Paramecium* species that shared a single resource. Gause found that one species always went extinct when both species were put together, suggesting that, as the Lotka-Volterra theory predicted, coexistence of two competitors is possible only in special cases. In 1946, however, Cromie placed two beetle competitors in a mixed environment of flour (i.e., resources) and small pieces of fine glass tubing (i.e., environmental complexity) and found that the species coexisted. Interestingly, in the absence of tubing coexistence was not possible, and one species always drove the other to extinction in those instances. Cromie's experiments suggest that some factors or influences that are not found in the simple Lotka-Volterra model may be important in facilitating coexistence. Since the time of Gause and Cromie, many other ecologists have studied the role of competition in natural ecosystems. In the early 1980s, Schoener and Connell each reviewed the literature for the prevalence of competition and found that a majority of published field studies successfully detected the impact of competition on the population dynamics of species (Connell, 1983; Schoener, 1983). A second review a decade later confirmed these findings but found a wide range of competitive effects with significant differences in the strength of competition among habitats and different types of species (Gurevitch *et al.*, 1992).

Predation

Predation is the consumption of one species by another. Consumption leads to a negative effect on the population of one of the two interacting species, known as the prey, and a

positive effect on the second population or species, known as the predator (Table 1). Also as in competition, predation has a rich history of mathematical theory, beginning with the work of Volterra. The predator–prey interaction is modeled with two equations: one for the prey (species 1) and one for the predator (species 2). Again, the components of these equations are discussed without going into great detail

$$\begin{aligned}\text{Species 1 : } \frac{dN_1}{dt} &= rN_1 - aN_1N_2 \\ \text{Species 2 : } \frac{dN_2}{dt} &= baN_1N_2 - dN_2\end{aligned}$$

According to this model, in the absence of a predator, species 1 would grow exponentially according to the rN_1 portion of the first equation; unlike the Lotka–Volterra competition equations, no carrying capacity limits growth in this model. This type of growth is called density independent. In other words, the rate of increase in the prey population remains constant through time and is independent of the number of individuals in the two populations. (Again, r represents the intrinsic rate of growth.) The number of prey removed from the prey population by predation is represented by the term aN_1N_2 , where a describes the fraction of encounters between predator and prey that ultimately result in kills. Predators consume prey for a single purpose – to produce new predators. The number of predators born (i.e., new predators added to the N_2 population in the second equation) is a function of how efficient predators are at producing offspring than from consuming prey. The variable b describes this efficiency, and the term baN_1N_2 thus represents births into the predator population. In this model, prey die only from predation, but predators die from other causes, and this death rate is the variable d . The number of individuals removed from the predator population due to death is the term dN_2 , and the fraction of predators removed is constant through time.

Several outcomes are predicted from this simple model. First, predators can drive prey to extinction by consuming them faster than prey can reproduce. Second, the predators can go extinct if their death rate exceeds their ability to produce new predators from the consumption of prey. Lastly, coexistence is possible. However, unlike the competition situation discussed in the previous section, these predator–prey equations do not reach a stable and persistent number of predators and prey in cases of coexistence; instead, the abundance of each species cycles through time. These cycles are called oscillations, with the predator abundance lagging behind that of the prey. As the number of prey increases, it is followed by an increase in the number of predators, driving a decrease in prey, and in turn driving a decrease in the number of predators. Once the predators decrease, the pressure of predation declines and prey can increase again, and the cycle repeats. The cyclic dynamics of predator–prey can be seen in Figure 3.

To determine whether the oscillations predicted by the Volterra theory reflect the true nature of predator–prey interactions, researchers have sought evidence of population cycles in nature. The most well-known example of predator–prey oscillations was shown in lynx feeding on hare in Canada. Recent evidence, however, calls into question whether or not the oscillations observed in the lynx–hare system are, in fact,

Figure 3 Sample diagram of a predator–prey system as predicted by the Volterra equations. N is the number of individuals $\times 103$ and t is time. The solid line, $N(1)$, is the number of individuals in the prey population, and the dashed line, $N(2)$, is the number of individuals in the predator population. Both predator and prey coexist in this diagram because neither goes extinct. The abundance of predator and prey is not stable through time but goes through oscillations or cycles. Notice that increases and decreases in predator population size follow those of the prey.

caused by a predator–prey interaction or by some nonpredation factor affecting hares, such as seasonal food shortage.

There is agreement that, oscillating or not, predator–prey interactions are common and are often strong. For example, following the extinction of many important large forest predators in conjunction with human alteration of the forested landscape, eastern US deer populations expanded to extraordinarily high levels. This suggests that predators once played a large role in suppressing the numbers of deer. A second example is the introduction of the brown tree snake to the island of Guam. In this case, the snake decimated the island's bird community, driving most of its prey to local extinction.

Several factors that are not included in the Volterra model can influence the dynamics of a predator–prey interaction, increasing the likelihood of coexistence and dampening cycles. Environmental spatial heterogeneity in abiotic and biotic factors can benefit either predators or prey. For example, in some portions of a species' habitat, it may be more difficult (or easier) to find or capture prey. It is also possible that the Volterra model does not reflect the true nature of a specific predator–prey interaction. For example, it may be unrealistic to model some prey species as density independent. Researchers have modified the Volterra model in many ways to increase its realism, including versions that incorporate density-dependent growth of prey.

Parasitism and Herbivory

Several other types of interactions have effects similar to those of predation, where one species benefits to the detriment of another. Herbivory, the consumption of plants by animals, is a subtype of predation but differs in some important ways. First,

most herbivores consume only a part of their prey, and consumption infrequently results in death. Second, plants cannot escape their predators as many animal prey do, changing the nature of the predator–prey interaction. Just as predators can greatly affect prey, herbivores play an important role in the dynamics of their host plants. For example, the introduction of the gypsy moth to the eastern US dramatically reduced the population size of many forest tree species, especially oaks and aspen. Also, the effects of herbivorous agricultural pests on crops are the impetus for widespread application of pesticide.

An interaction known as parasitism is also distinct from simple predation. Parasites are usually smaller than their prey (also called a host) and often feed on their hosts without killing them. When parasitic interactions are lethal, parasites kill their host after using or feeding on it for a period of time. Many human diseases such as malaria (a protozoan), intestinal round worms, and disease-causing trematodes such as liver flukes are parasitic. Viruses can also be considered a type of parasite. One interesting form of parasitism is a phenomenon known as brood parasitism in which one species of bird lays its eggs in the nest of another, leaving the offspring to be raised by a surrogate parent. In this case, the parasite does not consume the host but steals some of its parental care. Brood parasites, like all parasites, reduce the success and reproductive output of their hosts. An often fatal form of parasitism in many insect populations is infection by parasitic wasps or flies called parasitoids. These wasps lay eggs in the body cavity of their host; the parasitic larvae then feed on the host during development, killing it on emergence. Some types of parasitic interactions may have dynamics similar to those predicted by Volterra predator–prey theory. Recent evidence shows, for example, that cyclic red grouse populations in Britain may be driven by the effects of a nematode parasite on host reproductive ability.

Mutualism and Symbiosis

When both participants in an interaction benefit from their association, the interaction is known as mutualism (Table 1). Many types of mutualisms can be found in nature, and increasing evidence indicates that positive interactions may be more important than many ecologists previously considered in determining who can coexist in a community. There is relatively little theory about how mutualism promotes coexistence or how mutualistic species impact the population dynamics of one another, but a growing body of experimental evidence suggests that mutualism is common and important in ecological communities and, therefore, should be incorporated into our classic theories of community ecology (Bruno *et al.*, 2003). For example, many of the common interactions among organisms, such as animal pollination of plants and some animal dispersal of seeds, are mutualisms. Fruit-eating birds, for example, get nutrition from a plant in exchange for dispersing the plant's seeds across a wide area.

Mutualistic interactions can be facultative or obligatory. Facultative interactions are those in which neither species requires the other to persist but each benefits from the interaction when the opportunity arises. The association between a fruit-bearing tree and its avian visitors is facultative. Many

species of lycaenid butterflies have mutually beneficial and facultative associations with ants. The ants are thought to protect the larvae from predators whereas lycaenid larvae offer the ants a nutritious secretion in return.

Obligatory interactions are those in which each species requires the other for survival. These are typically highly specialized species associations. A classic pollination-based obligatory mutualism is that of the fig and fig wasp. Nearly every species of fig is pollinated exclusively by a specialized species of fig wasp, which lives inside the fig fruit. The fig rely on the wasps for pollination and the wasps rely on the fig as a habitat in which to execute their life cycle. Several plant species also have obligate mutualistic interactions with fungi. For example, many species of orchid require a fungal association for seed germination. The fungus, in turn, derives nutrients from the orchid. A third example is an obligatory interaction between some species of algae and fungi. The algae and fungus live together, creating an organism known as lichen.

The lichen example also illustrates a critical vocabulary point. Lichen is an example of a symbiotic mutualism. The terms “mutualism” and “symbiosis” are often used interchangeably, but they actually differ subtly. The term symbiosis stresses that two species live close to one another in prolonged association. Although many symbiotic interactions can also be mutualistic, this need not be the case. For example, you and the bacteria inhabiting your stomach which aide in your digestion are symbiotic and mutualistic, but you and the flukes feeding in your liver (if there are any) form a parasitic symbiosis.

Asymmetrical Interactions

One species can harm or help another species without any benefit or detriment in return. Commensalism refers to the benefit of one species, species A, from the presence of another species, species B, whereas B experiences no effect from the presence of A (Table 1). Conversely, amensalism refers to the detrimental effect of species B on A whereas B experiences no effect of A in return (Table 1). Far less research has focused on commensalism and amensalism than on other types of interactions, and the strength of commensalism and amensalism is generally thought to be weak. A famous example of commensalism is an association between cattle egrets and cattle. The egrets eat insects flushed by the cattle. The presence of the egrets, however, has no measurable effect on the cattle. Amensalism often occurs as the incidental damage to one species from the presence or activity of another. For example, in the cattle–egret example, some ground-dwelling insects suffer incidental mortality from the cows that step on them.

Interactions and Evolution

Previously, the direction of interaction effects and differences in interaction strength were discussed. It was also mentioned that interactions can change through time and space. In ecological time, interactions between species affect population size. In the longer term, however, interactions can lead to evolutionary change in the two participating species, either

reducing or increasing the strength of the association. For example, in competitive and predatory interactions, one species may evolve mechanisms to avoid strong interaction with others in response to the pressures of natural selection. In mutualistic interactions, on the contrary, specialized behaviors and morphology can be selected through time to promote efficiency, and species can grow to be more dependent on one another.

Evolution typically results from a pressure known as natural selection. Natural selection acts in the following way: Among a collection of organisms in a population, those individuals that are best suited for their environment will be the most successful and will produce a greater fraction of a population's offspring than will other individuals. Successful individuals will genetically pass their beneficial traits to their offspring if these traits are heritable. Through many generations of enhanced survival and reproduction of individuals with beneficial qualities, directional change in physiological, morphological, or behavioral traits at the population level can result. Natural selection can act in a variety of ways. For example, natural selection may favor traits that confer efficiency in food digestion or nutrient acquisition. Interactions between species can also be a force of natural selection for either or both species involved.

When natural selection results in reciprocal trait evolution in two interacting species, it is called coevolution. In other words, if morphological, physiological, or behavioral traits determined by genes in two interacting species evolve in response to an interspecific interaction, coevolution has taken place. The pressure of natural selection (called selection pressure) in coevolution stems from the positive or negative effects that species have on each other. Depending on the type of interaction driving coevolution (competition, predation, mutualism, etc.), many trait changes are possible.

Evolution and Competition

Remember that competition is thought to limit how similar two coexisting species can be. If, as seen in the Lotka-Volterra model of competition, resource overlap can drive one of two competitors to extinction, then competition can also be a strong selection pressure. Individuals with traits that enable them to compete less with other species can have an advantage compared to other members of their population. Over many generations of selection for minimizing overlap, populations can evolve away from interaction with their competitors.

The evolutionary change in a trait in response to competition is called character displacement. Character displacement results from selection for traits that reduce the overlap in resource use with a similar species. If two or more competing species evolve in response to one another, character displacement can be considered a type of coevolution. For example, in the Galapagos Islands, a group of coexisting finches have distinctly different body and beak sizes as well as beak shapes. Size specialization allows each finch to exploit a different food resource. The seemingly well-organized categories of finches suggest that there was once a strong influence of competition on these species and that competition drove the finches to evolve different strategies and diverge. In fact, the type of

pattern seen among finches on the Galapagos is widespread. Many species of similar type in a single habitat (e.g., desert rodents or island lizards) appear to be divided into distinct body size categories. This division suggests that selective pressure to reduce resource overlap was once (and may still be) an important influence.

It should be noted that the pattern of body size classes often seen in nature need not necessarily evoke character displacement as an explanation. An alternative hypothesis is the idea of selective retention of invaders. This hypothesis states that as a community is being filled by new arrivals to the system, those invading species that are able to persist are ones whose niche is currently vacant. In other words, invaders who find their niche already occupied are not able to persist in the system and go extinct shortly following invasion. This hypothesis is distinct from the character displacement hypothesis in which no evolutionary adaptation is necessary to explain the morphological differences seen among similar species.

Evolution and Mutualism

Change in morphologies in response to competitive pressure, as in the Galapagos finches, is one type of interaction-driven evolution. A second type can occur in mutualistic interactions. In mutualism, natural selection may favor those individuals that benefit more from an interaction than do other members of the same species. If the partner species in a mutualism is under analogous selective pressure, reciprocal, genetic changes in both species may result. Over many generations, coevolution increases the benefit each species gains from its interaction with the other.

Many plant-pollinator systems appear to have experienced some coevolutionary change. For instance, it may be advantageous for plants to attract pollinators that visit only a few or a single plant species, and many plants attract pollinators with specialized flashy petals and nutritious rewards. Because the next flower visited by such a specialist pollinator is more likely to be a member of the same plant species, a plant that attracts specialists enjoys an increased rate of successful pollination and a decreased expense of excess pollen production. Many pollination associations seem to be coevolved in this way, including hummingbirds with long curved bills feeding on species with long curved flowers and orchid species dispersing fragrances that attract specialized bee visitors.

Other coevolved mutualisms between animals and plants are also known. For instance, some acacia trees have mutualistic associations with ants. An ant colony resides in the tree and uses tree secretions called nectaries for food. The acacia uses the ants for protection from other insects and plants. Ants can attack herbivores that land on the plant, and in some cases the ants even remove competing plant material from around the acacia's base. Studies have shown that mutualistic acacias perform very poorly without ant inhabitants. Similarly, several species of ants are found only on acacia, indicating that for some, acacia is an obligatory ant resource.

In both the acacia-ant and plant-pollinator examples, it is difficult to imagine how such specialized associations could evolve without multiple steps of reciprocal morphological and

behavioral change. It is thought that specialized interactions evolved from generalized interactions, where survival and reproduction benefits of increased mutualism brought two select species closer together. Such increased association ended with, in some cases, obligatory dependence.

Evolution and Predation

Predators can place selection pressure on their prey to avoid capture, and the benefits of efficient catch and consumption of prey can drive the evolution of predators. The evolution of a trait in prey that makes predation more difficult can be followed by the reciprocal evolution of a trait in predators that reduces the prey's new advantage. Conversely, traits that confer advantages to predators can lead to increased natural selection on prey to evolve predation avoidance traits. Again, if two or more predators and prey evolve in response to one another, this is called coevolution.

Through evolutionary time, many species of prey have evolved defenses against predation, including the ability to flee, avoid detection, or being difficult to eat. Predators have also evolved techniques and physical characters to improve their efficiency or probability of successful capture of prey. Predators can become less conspicuous, faster, or more skilled at capturing and killing prey. This phenomenon was first discussed by Darwin in the late 1800s; he wrote of a constant struggle between prey to escape their enemies and predators to consume their prey. Today, we refer to the constant struggle as an evolutionary arms race, with the analogy to nations that reciprocally accumulate weapons to maintain an even balance of defense.

One frequently cited example of a coevolutionary arms race exists among plants and their herbivores. Plants must defend themselves against their predators since they cannot flee, and they often do so with chemicals called secondary compounds. These compounds either have a negative impact on the physiology of herbivores or decrease the ability of herbivores to consume the plant. Studies have shown that many plants increase the tissue concentration of secondary compounds in response to herbivory, suggesting that such compounds are indeed defensive. In addition, the presence of secondary compounds has been shown to effectively reduce the number of herbivores feeding on a plant. Some herbivores, however, have overcome the negative influence of secondary compounds by adapting ways to metabolize or resist the effects of the plant's defenses. Some herbivore species even use defensive compounds as a cue for identifying the plant as a food source. The pressure to evolve chemicals to escape herbivory, as well as the pressure to overcome antiherbivory compounds in order to sequester food, may have driven the degree of specialization seen in some herbivore-plant relationships.

A second example of a predation-like coevolutionary process can occur between brood parasites and their hosts. Recall that brood parasites lay their eggs in the nests of other species; parasite offspring hatch and are raised by the surrogate parent. Brood parasites place a selective pressure on their host to identify parasitic eggs and either remove them or abandon the nest. However, as hosts become better at recognizing parasitic

eggs, parasites are also selected to produce eggs that appear more similar to the host species. Parasites can become specialized on an individual host, producing eggs resembling only a single host species.

Multispecies Interactions

Limiting the treatment of interactions to two species helps us to classify associations and consider the effect an interaction might have on the evolution of participating species. In actuality, however, all organisms live in communities composed of more than two species. This reality is not reflected in the simple theories of competition and predation. Unfortunately, the addition of multiple species to simple models can quickly make them complex and difficult to manipulate. Despite these difficulties, a large body of empirical and theoretical work considers multispecies interactions and the role of multispecies interactions in driving evolutionary change.

Food Webs and Trophic Levels

One way to characterize interactions in a community is to document who eats whom. A food chain is a series of prey species and their predators (Figure 4). Food chains begin with plants (known as primary producers), followed by the animals that consume plants (primary consumers or herbivores), the animals that eat herbivores (secondary consumers), and so on. The collections of all food chains in a community comprise a food web. One can think of a food web as a diagram that describes how all species or groups of species in a community

Figure 4 General diagram of a food chain. All food resources originate from the energy of the sun. Primary producers use this energy to create plant biomass. Herbivores consume plants to create herbivore biomass. Carnivores, in turn, consume herbivores and other predators. Roman numerals represent different trophic levels; multiple species can exist within a single trophic level.

use one another for food (Figure 5). The positions (producer, secondary consumer, etc.) within a food chain or food web are known as trophic levels. Food webs and trophic levels are useful paradigms for thinking about species interactions; not only do they show the relationships among predators and prey but also suggest when species might compete or interact in other ways. Because organisms live in a world of multi-species interactions, food webs enable us to count interactions and consider the relative importance of multiple interactions on a single species.

Food webs can be very dynamic, even varying seasonally, but others are highly stable. Ecologists measure the robustness or resistance of a food web to change, and we call this robustness, stability. Specifically, stability refers to how a food web will respond to the removal, addition, or a large change in the population size of one or more community members. If the extinction of one community member is followed by the extinction of several other members, the web is unstable. If the web adjusts only slightly in response to extinction or large population shifts, it is stable. The issue of stability in food webs is important because the environment is very dynamic, and over long periods of time events such as large changes in resources or natural disasters are likely to occur. If a community persists through time, it must be resistant to such extreme events.

In 1972, May was the first to propose that webs with many members and many links were unstable. Using a mathematical model, May showed that the more interactions in a community, the greater is the potential for a small perturbation to affect multiple web members and the structure of the web. This result, however, seems counterintuitive because many of Earth's communities are diverse, with many species and many

Figure 5 A food web of inhabitants in a pitcher plant in West Malaysia. Pitcher plants have modified leaves that hold water and small communities of insects and microorganisms. All numbers except 16 (bacteria and protozoans), 17 (live insects that have fallen in the pitcher), 18 (drowned pitcher residents), and 19 (other organic debris) represent an insect species. Predators are higher in the web than are prey. For example, Nos. 17–19 are at the bottom of the food web, and they are preyed on by those species that are connected by a line and are higher in the diagram. Top predators are among the highest in the figures (e.g., 1, 3, and 4), and they prey on all species to which they are connected. Species that prey on some species but are also prey themselves can be found in the middle of the diagram (e.g., 8, 9, 12, and 13). Reproduced with permission from Pimm SL, Lawton JH and Cohen JE (1991) Food web patterns and their consequences. *Nature* 350: 669–674.

links. Also using mathematical theory, other researchers have shown that in certain cases diversity can lead to stability. For example, food web stability may be related to the asymmetry or symmetry of its interactions or to the location or arrangement of strong interactions in the web.

Keystone Species

A species that exerts a strong influence on the dynamics of several members of its community is called a keystone species. A keystone species' influence is one that is larger than we might expect based on its abundance alone. In other words, a keystone species must exert its influence based on the important interactions it has in the community and not simply on its dominance or high population size.

For example, the sea star, *Pisaster ochraceus*, is a classic keystone species in marine habitats of Oregon and Washington. It preys on several mussel species, including the mussel *Mytilus californianus*. Mussel species compete strongly for places to adhere on intertidal rocks. *M. californianus* is highly successful at dominating intertidal spatial resources, blocking out space needed by other mussel species. By feeding on *M. californianus*, *P. ochraceus* opens up rock space, resulting in an increase in the diversity of the community. In the absence of *P. ochraceus*, several species of mussel would be driven to extinction by the dominant competitor *M. californianus*, but in the presence of *P. ochraceus* the number of mussel species that can persist in the community is increased. Table 2 shows some experimental results of removing *P. ochraceus* from the intertidal zone in Washington.

Other predatory keystones include the sea otter and the bass; however, not all keystone species are found at the tops of food chains. For example, nitrogen-fixing bacteria may be keystone members of forest communities if they increase diversity by reducing the effects of nitrogen limitation. Beavers influence species diversity in their communities by altering the habitat structure of streams and ponds. Because keystones maintain the biodiversity of their communities, identifying and preserving them is an important conservation goal. To date, however, there is no general theory that predicts which members of a community will be keystones. The only way to identify a keystone species is to study its community in detail and the community effect of its removal.

Trophic Cascades and Indirect Interactions

Keystone species exert their strong influence on community composition by a combination of direct and indirect effects. Each of the interactions previously discussed (see Pairwise Interactions) in the context of pairwise interactions were direct – two species in contact and each influences the dynamics of the other. An indirect interaction occurs when species influence one another through their interactions with other species. Many different types of indirect interactions have been identified, including apparent competition, interaction modifications, and trophic cascades (Vandermeer, 1969; Wootton, 1994).

Apparent competition is the case in which two prey species share a single predator. If one of the two prey species were to increase in abundance, an increase in predator population size

Table 2 Species composition in the presence and absence of *Pisaster ochraceus*

	Suvery date

Total % covered ^c	89	85	100	100

^aPlots were of two types: those in which *P. ochraceus* was removed (removal) and those in which *P. ochraceus* remained (control).

^bAll species are sessile invertebrates or algae that live on the rocks of the intertidal zone.

^cNumbers do not necessarily total 100%; remaining space was either unoccupied or held by a few rarer species.

might follow. An increase in predators can then lead to a decline in both prey species. For example, an increase in the number of one of two grasshopper species has been shown to increase the number of parasitoids infecting both host species. Interaction modification is the case in which one species changes the interaction of two directly interacting species. For example, the amount of phytoplankton (small green plants) in the water column of a lake may affect a predatory fish's ability to find and capture a prey species.

A trophic cascade refers to the effects on several species in a food chain in response to a change in the population size of a single chain member. Trophic cascades were first discussed by Hairston *et al.* (1960), and the effect of cascades on population sizes at each level in a food chain was thereafter named the Hairston-Smith-Slobodkin (HSS) hypothesis. HSS predicts that predators indirectly control the abundance of primary producers by reducing the numbers of herbivores through predation and releasing producers from some herbivory pressure. Predation on herbivores keeps herbivore abundance low, and a smaller number of herbivores consume fewer producers than they would in the absence of predators. Empirical data support the HSS claim that predation can limit the consumption of producers in some systems. For example, as mentioned previously, after humans caused the local extinction of large predators, some herbivore densities (such as that of eastern deer) greatly increased. The increase in herbivores has in turn increased the amount of herbivory damage to forest plant species and has changed forest plant dynamics.

Trophic cascades can also be expanded to four trophic levels. For example, in lakes with piscivorous (fish-eating) fish, there is a decrease in the number of planktivores (plankton-eating fish), an increase in the number of herbivores, and a decrease in the amount of green phytoplankton in comparison to lakes without piscivores. This alternating suppression and release of predatory pressure might explain why some lakes are green and others are clear; water clarity (i.e., the amount of phytoplankton) may be determined, in part, by the number of trophic levels in the lake food web.

Metacommunities

Many of the historic theories and examples in community ecology, including food web theory and theories about the relationship between community diversity and stability, consider a single community in a single location. In recognition that communities are often highly dynamic and interconnected across geographic space, a framework has recently emerged to describe interactions among communities themselves. These metacommunities are collections of communities that are linked by dispersal of multiple, potentially interacting species (Leibold *et al.*, 2004). The metacommunity concept has arisen, in part, to enhance predictions about species interactions at larger spatial scales.

Multispecies and Evolution

Just as direct and pairwise interactions can influence evolution, species assemblages may influence selection pressures as well. Multiple and indirect effects, however, can select traits in complicated ways (Miller and Travis, 1996). In multispecies assemblages, many interactions can simultaneously place evolutionary pressure on a species. Where these pressures counterbalance, no change in morphology or behavior may result. When the pressures coincide, evolution by natural selection may occur. In general, a trait will be selected if an organism benefits from possessing the trait over the sum total of all its interactions. There are many examples of evolution in the balance of multiple pressures. For example, a mutualistic interaction between a lycaenid butterfly and its associated ants may have arisen in response to the pressures of parasitic infection of larvae by parasitoids (Pierce and Mead, 1981).

Human Impacts on Interactions

Many important services and goods used by humans result from species interactions. Services include pollination of

plants and the maintenance of soil fertility, and the products of these services provide goods such as agricultural crops, timber, and clean water. Increasing evidence suggests that human influences on the environment are impacting the very interactions that create these useful goods and services. Influences such as climate change, alteration of the earth's biogeochemical cycles, habitat loss, overharvesting, and pollution can cause disassociations among once-interacting species or change the nature of a service-providing association.

Human stresses on the environment can drive local extinction, and via species interactions single extinctions can impact multiple community members. Stresses such as climate change are changing the abiotic environment in a systematic way, forcing local extinctions in some areas and population expansion in other areas. The responses of individual species to these changes are unique, shifts in species ranges can result, and the overlap of species can break down and new ones can form.

For example, historical data show that vegetation responds very slowly to regional temperature change, and rates of plant species migration will be slow in response to global warming. Some insects, however, have the potential for long-range dispersal and will respond to climatic changes more quickly than plants will. If insects shift faster than plants, some plant populations may be left without pollinators. Furthermore, even if interacting species, such as plants and insects, were able to shift at the same pace, other stresses such as habitat fragmentation stand in their way. If one species is able to shift over a fragmented landscape and another species is not, disassociation can result.

Humans can alter the timing of interactions as well as the ability of species to persist in the same geographic location. For example, evidence suggests that human influences on biogeochemical cycles, including increases in anthropogenic nitrogen deposition, can impact the growth rate of plants, affecting their flowering and development timing (i.e., phenology). Changes in plant phenology may affect the temporal overlap between herbivores and their food plants, possibly leading to herbivore population decline.

Lastly, human domination of the earth has greatly increased the distribution of a few, particular species. Many organisms travel with people as they disperse throughout the world, and some of these species have established themselves in locations other than where they originally evolved. These species are often dominant competitors; they spread quickly and displace other organisms. Because they drive native species extinct or harm native populations, such introductions have significantly altered native interactions in many parts of the world. For example, the introduction of European grasses to California has excluded native plants from all but very small relic patches throughout the state. The loss of native plants has in turn affected the viability of many herbivores that are specialized to forage on native California plants.

An alarming number of Earth's species are going extinct at the hand of human civilization. Identifying and conserving keystone species, as well as predicting and preventing extinction cascades, will be critical to successful mitigation and evasion of further biodiversity loss. To preserve the interactions and communities we need, community ecologists will be asked to provide predictive and restorative information on

a great diversity of community and interaction types. Ecologists also will be asked to increase the generality of their findings because species are going extinct more quickly than we can identify taxa and describe communities.

Summary

Species interactions are classified by the direction of their effects and are divided into the direct pairwise categories of competition, predator-prey, mutualism, commensalism, and amensalism (**Table 1**). The strength of an interaction or the amount an interaction affects the population size of its participants, can be determined by experimentally removing one species and observing the population response of the second species and vice versa.

A simple mathematical theory for competition predicts that the amount of resource overlap between two coexisting, competing species must be small (**Figure 2**). A simple mathematical theory for predation predicts that for coexisting predators and prey, population sizes will oscillate through time (**Figure 3**). In both cases, theory may oversimplify the opportunities for species coexistence. Factors such as variation in resources, space, and time, as well as the complexity of a habitat, can minimize resource overlap among competing species or dampen predator-prey oscillations. Mutualistic or positive interactions do not have a historic theory for predicting when and where they will occur, but mutualisms are common in nature.

Pairwise interactions between species can select for changes in morphological, physiological, and behavioral traits through evolutionary time. Coevolution occurs when there is reciprocal genetic change between two interacting species. Coevolution in competitive systems can lead to character displacement. Coevolution in predator-prey systems can lead to an arms race of capture and escape. Also, coevolution in mutualistic systems can lead to highly specialized associations between mutually benefiting species.

Communities are composed of many species, and indirect as well as direct interactions control community composition (**Figure 5**). Indirect interactions include trophic cascades, apparent competition, and the modification of a direct interaction. A keystone is a species that strongly influences the biodiversity of its community via indirect and direct effects (**Table 2**). keystones are often, but not always, found at the top of a trophic chain or food web. Both indirect and direct interactions can influence the evolution of community members.

Humans are causing widespread extinction of species, and the loss of species is leading to the decline of many goods and services provided by species interactions in natural systems. Human stresses on the environment, such as climate change, alteration of geochemical cycles, and destruction of habitat, can break down species associations because individual species, not communities, respond to changes in the environment.

Glossary

Relative abundance distribution The frequency distribution depicting the number of species in a community as a function of the number of individuals comprising each species.

Species–area curve A graphical depiction of the dependence of species richness on area.

Species–area model A function used to describe species–area curves.

Species–area relationship The dependence of the number of species in a sample region on the area or size of the region.

Introduction and Underlying Mechanisms

Watson first described the species–area relationship in 1835 by remarking that as the area of a county in England increases by a factor of 10 the number of plant species found in that county increases by a factor of 2 (**Figure 1**). The long history of discourse on species–area relationships has evolved from a focus prior to the 1960s on its empirical utility in determining the optimal sample size and sample number for community description, for determining the minimum area of a community, and in extrapolating predictions of species richness to areas larger than those sampled to a focus in the 1960s and 1970s on the mechanisms underlying the species–area relationships, in finding the best mathematical model for species–area relationships, and in explaining species–area relationships in the context of the equilibrium theory of island biogeography (**Connor and McCoy, 1979**). Since 1980, the primary focus of discussion involving species–area relationships has been their use and application in conservation biology to determine the optimal design of nature reserves and to project the expected loss of species richness from a region undergoing specified levels of area reduction (habitat loss). We review the discourse on species–area relationships beginning in the 1960s and focus our synthesis on the application of species–area relationships in conservation biology.

Three biological mechanisms have been proposed to account for the species–area relationships: (1) the habitat diversity hypothesis, (2) the area per se hypothesis, and (3) the passive sampling hypothesis.

The Habitat Diversity Hypothesis

The habitat diversity hypothesis (**Williams, 1964**) proposes that the increase in species richness in large areas relative to small areas arises because large areas have a greater variety of habitats than small areas. This greater variety of habitats permits species that are only found in specific habitats to occur in large areas and permits species that require multiple habitats to persist in large areas, resulting in higher species richness in large areas than in small areas and the existence of species–area relationships. The habitat diversity hypothesis views area as affecting species richness indirectly because of its

association with habitat diversity rather than any direct effect of area on the ability of species to colonize or persist in larger areas. Studies that demonstrate positive correlations between the number of species and the number of habitats on an island have been viewed as supporting the operation of the habitat diversity hypothesis.

The Area Per Se Hypothesis

The area per se hypothesis (**Simberloff, 1976**) is based on the assumptions that the abundance of each species in a sample region varies as an increasing function of that region's area and that the probability of each species going stochastically extinct there is a decreasing function of abundance, and therefore of the area. Given these assumptions, large areas would have more species than small areas because more species would persist (not go locally extinct) in large areas. The area per se hypothesis suggests that even in a group of patches consisting of a single type of habitat, one would observe a species–area relationship. Correlations between species richness and area in studies that purport to examine a single habitat type and experimental studies that examine the

Figure 1 Species–area curve for the vascular plants of the Galapagos Archipelago. The logarithm of species richness is commonly plotted as a function of the logarithm of area, but species richness may also be plotted as a function of area or log(area).

consequences of reducing patch area are viewed as evidence supporting the operation of the area per se hypothesis.

The Passive Sampling Hypothesis

The passive sampling hypothesis (Connor and McCoy, 1979) conjectures that larger areas are more likely to receive more colonists than smaller areas and that these colonists are likely to represent a wider array of species than the pool of colonists arriving on small areas. Therefore, purely as a result of the higher abundance of colonists expected for large areas and independent of any increase in habitat diversity or reduction in extinction probabilities, one would expect more species to arrive on large areas, leading to species–area relationships. Several authors have examined the number of colonists arriving at their study sites and concluded that passive sampling accounts partially for the species richness of invertebrates on intertidal boulders, fish in stream pools and riffles, and birds on forest habitat islands. Each of these studies shows that for habitats that are colonized seasonally, those patches receiving more colonists have higher species richness.

Two other area-dependent factors that affect species richness have recently entered discussions concerning species–area relationships, particularly for habitat patches: the resource concentration hypothesis and edge effects.

The Resource Concentration Hypothesis

The resource concentration hypothesis attempts to explain the phenomenon that habitat patches with large amounts of resources (e.g., monocultures, areas of high plant density, or large patches) have higher densities of insects. Therefore, the resource concentration hypothesis conjectures that population density should be positively correlated with patch area. In 1973, R.B. Root conjectured that the higher density of animals in larger patches might be solely a consequence of movement behavior (the movement hypothesis); herbivores are more likely to find, and remain in, large, monospecific stands of their host plant than in small or heterogeneous patches. If many species have higher population densities in large patches because of the resource concentration hypothesis, then extinction probabilities should be even lower than expected from the area per se hypothesis, and hence resource concentration could contribute to observed species–area relationships. E.F. Connor and co-workers have recently reviewed the existing literature on the relationships between animal population density and patch area and found that for insects and birds positive area–density relationships are common, but not so for mammals.

Edge Effects

Edge effects, or habitat edge dependent changes in abundance or risk of mortality, have been reported for species in a variety of taxa in habitat patches. Given that the proportion of a patch that occurs within any fixed distance from its edge is inversely related to the area, edge effects could lead to species–area relationships even within a single habitat type. Such an edge effect on species richness would be mediated by a reduction in the abundance of a species on small patches because of a larger amount of “edge habitat”, leading to higher

probabilities of local extinction. Therefore, part of the dependence of species richness on area that has previously been attributed to area per se may actually be caused by edge effects.

Multiple Causes of Species–Area Relationships

Habitat diversity, area per se, passive sampling, edge effects, and resource concentration are not mutually exclusive mechanisms and may operate individually or in combination to cause species–area relationships (Connor and McCoy, 1979). Experiments on invertebrate colonization on artificial substrates of varying size and habitat diversity clearly demonstrate the joint contribution of habitat diversity and either the area per se or passive sampling hypothesis, or both, to the generation of species–area relationships. Studies that subsampled islands using a constant-sized quadrat on each island in an attempt to eliminate the effect of habitat diversity found strong effects of habitat diversity, but species richness remained an increasing function of island area even for the data derived from constant-sized quadrats. Using path analysis, D.D. Kohn and D.M. Walsh concluded that area had both a direct effect on species richness (area per se and/or passive sampling) and an indirect effect mediated by the effect of area on habitat diversity.

The evidence that would allow one to clearly partition the causes of a specific species–area relationship among these underlying mechanisms is exacting. Habitat diversity is difficult to measure, and edge effects might make it impossible to separate the effects of increasing area from the effects of area on habitat diversity. The area per se, resource concentration, and passive sampling hypotheses act by affecting the abundances of species on an island. Area per se and resource concentration do so by reducing extinction probabilities via allowing larger populations (or more dense populations) to persist on large islands, and passive sampling does so by proposing that greater numbers of colonists arrive on large islands. To demonstrate an effect of area per se or resource concentration, one must ultimately show that species on average have larger population sizes (or in the case of resource concentration, higher population densities) and lower extinction probabilities on large islands or habitat patches. To demonstrate an effect of passive sampling, one must show that the arrival rate of colonists on large islands or habitat patches is greater than for the small patches and that the colonizing individuals arriving on large patches comprise a greater number of species than those arriving on small patches. To demonstrate that edge effects contribute to species–area relationships would require evidence that species absences from small patches could be uniquely attributed to edge effects and not to the alternative mechanisms discussed above.

Sampling and Statistical Practice in Description of Species–Area Relationships

Sampling Practice

Two main sampling schemes have been used to generate data on the relationship between species richness and area. The most widely used approach has been to sample physically separated areas such as islands or habitat patches or to sample

Figure 2 Independent and nested sampling designs used in species–area studies. Independent areas are physically separate. Nested areas may be serially self-contained as in A or abutting as in B. If abutting areas are used, then the sampled region is partitioned into a series of equal-sized, adjacent areas, and this process is repeated for the range of different sized areas. Only two areas are depicted in B, one with six replicates and one with three.

adjacent or abutting areas of continuous habitat as independent, nonoverlapping replicates (Figure 2). For physically separated areas, sampling from the observed natural range of areas generates a range of sample areas. For continuous habitat, the region is divided arbitrarily into a series of nonoverlapping subregions to generate a range of sample areas. The alternative approach, which has been used widely by plant ecologists, is to enumerate the locations of species within a larger region and generate a sample of areas by subsampling a range of areas within the larger region. These subsamples may or may not overlap, depending on the choice of the researcher (Figure 2).

Independent Areas

Physically independent sample areas have been widely used because species–area data could be readily generated for natural geographical units, such as islands, by combining published monographic species lists with published data on island areas. The majority of species–area curves were published in the 1960s and 1970s by the scientists gleaning existing data from the monographic literature and combining data on species richness with published estimates of area. Species–area curves based on gleaned data could be produced relatively quickly from a library. Another advantage of using physically independent sample areas is that they are arguably statistically independent. The statistical independence of separate, nonoverlapping areas allows use of the methods of statistical inference and hypothesis testing associated with ordinary least-squares (OLS) regression. The application of OLS regression permits the estimation of the parameters (and their standard errors) for any of the proposed functional forms of

the species–area relationship that could be made sufficiently linear by transformation of the data and an assessment of the statistical significance of the fit of a particular model. Furthermore, the use of statistically independent areas allowed the rigorous comparison of parameter estimates between studies via analysis of covariance or other simpler techniques.

Nested Areas

Plant ecologists have generated data for many years on the relationship between species richness and a plot or quadrat area for a variety of plant communities. Much of this work was done to determine the optimal plot size to use when describing plant communities. Presumably because of the saving in sampling effort, plant ecologists used serially self-contained or nested quadrats rather than physically independent quadrats to determine optimal quadrat size. However, nested quadrats are not statistically independent so it will be inappropriate to use OLS regression to fit a linear model to such data and assess the fit of the model or estimate its parameters. Therefore, use of nested quadrats to examine species–area relationships in plant communities was largely discontinued by the end of the 1970s. Recent research programs aimed at understanding the structure and dynamics of tropical forests have once again led to the studies of species–area relationships using nonindependent data. However, Condit et al. (1996) partition their largest quadrat into as many equal-sized quadrats as possible and use the mean for all nonoverlapping quadrats to estimate species richness for that quadrat size. They repeat this process of partitioning their large quadrat (50 ha) into the maximum possible number of nonoverlapping subquadrats for a variety of quadrat sizes. Condit et al. (1996) then plot the mean and standard error of species richness for each quadrat size as a function of quadrat area to produce a species–area curve. This approach leads to appropriate estimates of species richness and its standard error for each individual quadrat size, since within a size category the quadrats used to estimate the mean and standard error of species richness are independent. However, since the same sampled area is used to estimate species richness for each quadrat size, these estimates are not statistically independent and Condit et al. (1996) appropriately refrain from using regression techniques that require independence to fit statistical models to species–area data.

Statistical Practice

OLS regression has been used to fit models to species–area data. By applying OLS regression, estimates of the model's parameters and their associated standard errors can be obtained readily. If one makes the additional assumptions that the model's errors are independent, homoscedastic, and normally distributed and that species richness or the logarithm of species richness is a linear function of area or its logarithm, then rigorous statistical inferences about the parameters may be made. In recent years, nonlinear regression procedures have become widely available so that inherently curvilinear species–area models may be directly fit to the data. Nevertheless, OLS regression continues to be used widely.

P.J. Vincent, J.M. Haworth, and M.R. Williams point out that the assumptions of normality and homogeneity of error variances are unlikely to be met by species–area data. First of all, species richness is unlikely to be normally or log-normally distributed and probably should be treated as a discrete, rather than a continuous, variable. Second, the variance in species richness is likely to be a function of the mean species richness. These properties arise partially because on very small areas both the mean and variance of species richness must be nearly zero. P.J. Vincent and J.M. Haworth suggest analyzing species–area data using a generalized linear model and treating species richness as a Poisson-distributed variable. Williams also suggests analyzing species–area data using a generalized linear model but recommends that species richness be treated as a binomially distributed variable (*see discussion in Extreme Value Model and Random Placement*). In both the cases, parameters and their standard errors can be estimated and rigorous statistical inferences can be made. Since 2000, many authors have applied generalized linear models to the analysis of species–area relationships. Williams et al. (2009) summarize this literature and make sound recommendations for model fitting and model selection.

Functional Form of the Species–Area Relationship

When species richness is plotted as a function of area, the resulting plot is a curve that may be linear, concave downward,

concave upward, or sigmoid (Figure 3). The shape of species–area curves appears to be a function of the particular range of areas studied, and this may, in part, explain the variety of transformations used to linearize species–area curves.

Historically, much of the discussion of species–area relationships focused on the specific functional form of the relationship between species richness and area. In 1921, Arrhenius proposed that species–area relationships followed a power function (Figure 3(b)): $S = cA^z$ which, for statistical convenience, has commonly been approximated by the log–log transformation: $\log S = \log c + z \log A$ with c and z as constants. The double-logarithmic transformation linearizes the power-function model, so that species–area curves are linear on a double-log plot (Figure 1). In 1922, Gleason championed an exponential model of the species–area relationship (Figure 3(c)): $S = \log c + z \log A$ because he observed the power-function model to predict impossibly large numbers of species for large areas. The exponential model produces species–area curves that are linear on a semilogarithmic plot. Both of these models were supported because they seemed to fit specific data sets using independent areas reasonably well and because it was argued that they could be derived as a consequence of assuming that the distribution of individuals among species (the relative abundance distribution) was either log-normal or log-series, respectively. Other ecologists reported that when a wide range of areas were sampled, neither the power-function model nor the exponential model fit

Figure 3 Shapes of species–area curves encountered in empirical studies: (a) linear species–area curve; (b) concave-downward species–area curve (linearized by the log–log transformation); (c) concave-upward species–area curve (linearized by a semilogarithmic transformation, area log-transformed); (d) sigmoid species–area curve (usually not transformed). Linear curves are encountered at intermediate spatial scales, concave-downward curves at larger spatial scales, concave-upward curves at small spatial scales, and sigmoid curves when a wide range of spatial scales is studied.

their data since species–area curves appeared sigmoid in shape (Figure 3(d)).

Connor and McCoy (1979) examined the fit of the power-function model, the exponential model, and two other models to data from 100 species–area studies. They found that although the power-function model often fit the data well, it was not found to be the best fit model substantially more often than other models. Based on this analysis, the observation that the log–log transformation can linearize a wide range of curves, and because of its widespread use, Connor and McCoy (1979) recommended the continued use of the power-function model of species–area relationships.

Recent discussions of the functional form of the species–area relationship have continued to promote the use of the power-function model but have continued to justify its use because of its hypothesized connection to log-normal relative abundance distributions (Rosenzweig, 1995). Given a common log-normal relative abundance distribution from which the abundances of species on all sites (islands or habitat patches) arise, it is possible to derive species–area data that are reasonably well fit by a power-function model. However, simply because a particular set of species–area data is reasonably well fit by a power-function model does not imply that this fit derives as a consequence of sampling from a common log-normal relative abundance distribution (Hanski and Gyllenberg, 1997). Many island archipelagos are colonized from multiple source regions rather than from a single source pool, and individual islands within such archipelagos may receive different proportions of their colonists from each source. However, habitat patches may be more accurately viewed as units whose species composition is determined by sampling from a source pool with a single relative abundance distribution.

Continued debate about the functional form of the species–area relationship assumes that underlying the variability we observe in empirically estimated species–area curves lies a single true function that will characterize this relationship. However, most data on species–area relationships using independent areas have small sample sizes, cover a narrow range of areas, and may be confounded by area-dependent sampling effort, among other problems. Given the quality of the data available, it will be difficult to discern the functional form of the species–area relationship, even if a single form exists. Furthermore, it is possible that differences among taxa or spatial scales could generate species–area relationships of different functional forms.

Self-Similarity and the Power-Function Model of Species–Area Relationships

Harte and co-workers have recently proposed an alternative derivation of the power-function model of the species–area relationship. This derivation comes from examining nested areas and making the assumption that successive partitions of a continuous area have the fractal property of self-similarity. That is, the distribution of species in successive partitions is independent of the spatial scale. Beginning with a large continuous area A_0 with S_0 species, bisections of A_0 such that the rectangles comprising the two halves of A_0 have an area

$A_i = A_0/2^i$ each will have on average S_i species, where i indicates the i th bisection of A_0 . The assumption of self-similarity requires that a species known to be in A_i will have probability a of being found in at least a specific one of the two rectangles of area A_{i+1} created by bisection, and therefore the fraction of species found in A_i that are found in a specific one of the A_{i+1} rectangles equals the same constant a for all i bisections. The constancy of a for all i bisections follows from the assumption of self-similarity since a , the probability of occurrence in a half-patch under bisection, must be independent of spatial scale. Harte et al. (1999) show that the assumption of self-similarity leads directly to the power-function model of the species–area relationship: $S_i = cA_i^z$, with the self-similarity parameter $a = 2^{-z}$. Furthermore, since under successive bisections of an initial continuous area the value of a must lie between 0.5 and 1, the relationship between a and z dictates that the slope of the power-function model, z , must lie between 0 and 1. Hence, the power-function model of the species–area relationship is derivable without recourse to any assumptions about the underlying relative abundance distribution of species.

Harte and colleagues have extended the assumption of self-similarity to generate an expectation for the relationship between the number of endemic species and area and the expected spatial turnover between two patches isolated by a known distance, d . These extensions of the assumption of self-similarity provide a basis for estimating the expected loss of species from areas undergoing habitat reduction, for calculating z from spatially separated sites, and for estimating species richness at spatial scales larger than commonly possible in previous studies of species–area relationships. However, as Harte and colleagues point out, the assumption of self-similarity is not likely to hold for a wide range of spatial scales, so care must be taken to test the assumption of self-similarity for the taxa and spatial scales of inference. Although Harte and colleagues have published a few examples where the assumption of self-similarity seems reasonable over a specific range of spatial scales, Plotkin and colleagues show that tropical forest trees are not self-similar in distribution over spatial scales from 1 to 10^5 m^2 .

Extreme Value Model and Random Placement

An alternative model of species–area relationships based on random placement was first proposed by Coleman in 1981 (Coleman et al., 1982) and extended by Williams (1995). The random placement model of species–area relationships derives the expected number of species on a site, $\bar{s}(\alpha_k)$, of area A_k as a consequence of placing the n_i individuals of the i th species on sites independently and at random with probability: $\alpha_k = A_k/A_t$, where A_k is the area of the k th site, A_t is the combined area of all sites, and S is the total number of species among all the sites:

$$\bar{s}(\alpha_k) = S - \sum_{i=1}^S (1 - \alpha_k)^{n_i}$$

As presented by Coleman et al. (1982), data on the total abundance of each species combined among all sites were required to estimate the expected species–area curve under the

random placement model. Because the random placement model required data that ecologists seldom have, censuses of the abundances of each species at each site, and because this model does not yield fitted parameters comparable to other species–area models, few authors attempted to fit the random placement model to their data.

Williams (1995) extended and adapted the random placement model to be approximated by an extreme value function which permits model fitting within the context of the generalized linear model and requires data only on species richness and area, not on the abundances of the individual species. The extreme value function model of species richness, $\bar{s}$, in $\log A$ is then $\bar{s} = P[1 - \exp(\gamma \log A + \log d)]$ with P being the number of species in the species pool, and γ and $\log d$ the slope and intercept of the model, respectively. Williams (1995) outlines a method for estimating P if the species composition of the biota is unknown but suggests that the best estimate of P is the total number of species found. The extreme value function model has been fitted to a limited number of data sets but appears sigmoid when species richness is plotted as a function of $\log(\text{area})$. The random placement or extreme value function model of species–area relationships is appealing because it is derived from a hypothesis of independence within and between species. However, as Williams (1995) points out, discriminating between the power function and the extreme value function models with most existing data sets derived from sampling independent areas will be difficult.

Interpretation of the Parameters of Species–Area Models

The widespread use of the power-function model of the species–area relationship coupled with specific numerical expectations for its slope parameter, proposed by Preston in 1960, led to numerous attempts to infer biological significance to the values of this parameter. The slope parameter measures the rate at which species are added as area increases, and the intercept parameter has been considered a function of taxon-specific attributes and environmental variation. Only a limited attempt has been made to offer biological interpretations of the intercept parameter, partly because in the power-function model the absolute value of c depends on the units in which area is measured (Connor and McCoy, 1979; Rosenzweig, 1995). The parameters of other models of the species–area relationship have generally been treated as fitted statistical constants, with no attempt to interpret them biologically.

The slope of the power-function model of the species–area relationship and patterns of variation in this parameter have been subjected to considerable analysis and interpretation. Connor and McCoy critiqued many of these interpretations in their 1979 review. We will briefly examine a few of these interpretations and touch on those which are proposed very recently.

Canonical Slope Values

Preston proposed that isolated islands in equilibrium that sample colonists from a common log-normal relative

abundance distribution with parameter $\gamma = 1$ (Preston's canonical hypothesis) will have a slope of 0.262 in the power-function model. He subsequently broadened the range of slope values that he expected from isolates to values between 0.17 and 0.33. May showed in 1975 that using a wide range of log normal parameter values leads to power-function slope values in the 0.15–0.39 range. Many authors have generated slopes from the power-function model of the species–area relationship and interpreted values in the range of 0.2–0.4 to be consistent with Preston's idea that species–area curves arise because the species richness of islands results from sampling from an underlying log-normal relative abundance distribution. However, Connor and McCoy (1979) challenged Preston's idea of a canonical range of slope values by showing that slopes in the 0.2–0.4 range are expected purely as a consequence of the tendency to publish studies that show a high correlation between species richness and area and because the variance in species richness will always be less than the variance in area. Connor and McCoy (1979) concluded that slope values from the power-function model of species–area relationship in the 0.2–0.4 range could not be used as evidence for the existence of an underlying log-normal relative abundance distribution.

Island–Mainland Differences in Slope Values

Preston extended his idea that islands or isolates should have power-function slopes in the range of 0.2–0.4 to project that nonisolated or mainland areas should have lower slope values than isolated areas. His rationale was derived from the belief that nonisolated areas would sample from a truncated relative abundance distribution with a higher ratio of species to individuals. In their monograph *The Theory of Island Biogeography*, MacArthur and Wilson (1967) modified Preston's idea, suggesting a specific range to be expected for slopes derived from nonisolated areas, 0.12–0.19, and explaining the lower slopes as arising because of the transient hypothesis. The transient hypothesis suggests that more transient individuals will be encountered in small, nonisolated areas than in small, isolated areas, which, in turn, will lead to more species being encountered on small, nonisolated areas than on small, isolated areas. The greater number of species found on small, nonisolated areas would depress the slope of the species–area curve for mainland areas relative to that expected for islands. The available evidence, although limited, is consistent with the idea that power-function slopes for mainland areas are lower than those for islands.

Hanski and Gyllenberg (1997) develop dynamical models of species incidence that generate predictions about the slopes of species–area curves as a function of the moments of the relative abundance distribution and the ratio of species' colonization and extinction rates. Hanski and Gyllenberg (1997) develop two models, one in which sites are colonized from an external source, their island–mainland model, and one in which the sources of colonists are internal to the system of sites, their metapopulation model. They find that species–area slopes are lower for their metapopulation model and claim that such a model is analogous to mainland areas, whereas their island–mainland model is analogous to truly insular

situations. Hanski and Gyllenberg (1997) suggest that their models imply that the observation of lower slope values on mainland sites is a result of metapopulation dynamics rather than the transient hypothesis.

The Effect of Isolation on Slope Values

MacArthur and Wilson extended their transient hypothesis to predict that the slopes of species–area curves should be lower for distant archipelagos of islands than for islands located close to mainland areas. However, Schoener illustrated with species–area curves for birds in 23 archipelagos that exactly the opposite pattern occurs. Schoener's result suggests that the slope of species–area curves depends on the size of the source pool of colonizing species, which would be smaller for distant than near island groups. In other words, the low slopes for species–area curves observed for isolated archipelagos tell us no more than that isolated biotas are depauperate. Hanski and Gyllenberg (1997) suggest that Schoener's observation of lower slope values for isolated archipelagos arises because isolated archipelagos behave according to their metapopulation model, not as an island–mainland system.

Other Interpretations of Slope Values

Many other efforts have been made to explain variation in the slope of the power-function model of the species–area relationship. These efforts include (1) attempts to equate the slope of the species–area curve with β , or between-habitat diversity, and the intercept with α or within-habitat diversity, (2) attempts to predict patterns in the latitudinal dependence of the species–area relationship (both slope and intercept), and (3) attempts to identify taxonomic and trophic group differences in species–area curves, among others. Connor and McCoy (1979) critiqued many of the attempts to interpret the parameters of the power-function model of the species–area relationship and recommended that these parameters be viewed as fitted constants, with no specific biological interpretation.

Conclusions

Species–area relationships represent a pattern expected in nature that may arise from the colonization and development of quasi-independent biotas on islands or habitat patches (island–colonization model) or from the loss, reduction, and fragmentation of a previously continuous or widespread biota into remnant habitat patches (mainland–vicariance model). Historically, inquiry into the mechanisms underlying the species–area relationship and its functional form has been biased toward the island–colonization model. However, models based on self-similarity more closely represent the mainland–vicariance model and provide a basis to unify species–area relationships with other patterns in the geographical distribution of species (e.g., distribution and abundance relationships, compositional similarity among sites, and relative abundance distributions). Continued empirical study of the species–area relationships and inquiry into the functional forms expected under specific biological and sampling

models will continue to improve our understanding of spatial patterns of species richness.

Use of Species–Area Curves in Conservation Biology

What can an understanding of the species–area relationship contribute to the preservation of biodiversity? The question has interested ecologists for more than 30 years since the pioneering work of N.W. Moore, E. Maarel, and others and has led, almost from the beginning, to a bewildering confusion of missteps and dead ends (see Shafer (1990) for an overview). Implicit in this question are the important assumptions that species richness is the primary object of preservation and that area is the primary influence on species richness. Here, we shall explore two separate, but similar, aspects of the question. We shall see what ecologists have been able to conclude about the loss of species accompanying area reduction and what they have been able to conclude about the best way to slow the loss.

Loss of Species from Area Reduction

As we have illustrated, the species–area relationship is an extraordinarily common pattern in nature, and it has been documented numerous times. It would seem, therefore, that calculating the loss of species accompanying a certain amount of area reduction would be a rather straightforward exercise. All that one would need to know to perform the calculation would be the original number of species (S_{original}), the amount of area reduction ($A_{\text{reduced}}/A_{\text{original}}$), and the slope of the species–area relationship (z). For example, if one assumes a power-function model of the species–area relationship $S = cA^z$, then $S_{\text{original}} = c(A_{\text{original}})^z$, $S_{\text{reduced}} = c(A_{\text{reduced}})^z$, and, therefore, $S_{\text{reduced}}/S_{\text{original}} = (A_{\text{reduced}}/A_{\text{original}})^z$ (Figure 4). Although calculations of this sort are reasonably common, they require at least five assumptions. First area reduction completely eliminates species that were originally present (but some species may survive on relict fragments or disturbed lands). Second all of the species that were originally present were distributed homogeneously (but most species are unlikely to be distributed in this manner). Third an appropriate model has been selected to describe the species–area relationship. Fourth the slope of the species–area relationship is accurate and a constant (but it is not likely to be, for a number of reasons). Fifth the loss of species is a direct consequence only of area reduction (but it is not likely to be, for a number of reasons). The last two assumptions have received the most attention from ecologists. We shall discuss both of them further. Choice of the slope of the species–area relationship is critical. Clearly, if one knew the original number of species and area and the reduced number of species and area, then the slope would be determined precisely. The point of the calculations presented in this section, however, is to estimate potential species loss, before it happens, so the slope of the species–area relationship also must be estimated, from theory and empirical study. A great deal of uncertainty accompanies such estimation. First one must decide which model of species loss is appropriate. For example, if the relationship between

Figure 4 Loss of species richness under specified levels of habitat loss expected using the power-function model of the species–area curve. (a) Illustrates the single-large-or-several-small controversy calculation of the number of species expected for a single large reserve (SLR) of 1000 units of area (34.5 species) vs. the number of species expected for a reserve half that size (500 area units), 29 species. If the species lists from the two half-sized reserves do not overlap extensively, then the two half reserves should contain more species than the SLR. For this example, $S = 4.5A^{0.3}$. (b) The expected proportion of species lost when area is reduced by a fixed proportion as calculated using the power-function model of the species–area relationship for various values of z and $S = 4.5A^z$.

species and area were assumed to be linear (Figure 3(a)), then a much different rate of loss of species would be predicted to occur than if the relationship were assumed to be a power function (Figure 3(b)). Second one must assume that the slope of the species–area curve is constant between the spatial scales over which species loss is to be estimated. A non-constant slope value would suggest that an appropriate species–area model has not been completely specified and could lead to the substantial misestimation of species loss. Third one must decide if the reduced area better represents an isolate (a true island) or simply a subsample of the original area. Typically, slopes of species–area relationships are greater in the first case (approximately 0.20–0.40, on a log–log scale) than in the second (approximately 0.12–0.19, on a log–log scale). Further, it may be that the reduced area could come to function less like a subsample and more like a true island over time, so that the range of potential slopes could expand dramatically

over time. Fourth even if one managed to choose the more accurate of the two ranges of slope values, an impressive amount of variation would still remain. For example, with the equations presented earlier in this section, if area is reduced by 80% and $z = 0.20$, then species loss is estimated at 27%, whereas if area is reduced by the same percentage but $z = 0.30$, then species loss is estimated at 38%. Fifth even if one knew precisely the correct slope of the species–area relationship in one location at a time, Connor and McCoy (1979) and others have shown that the slope is not likely to be amenable to translation across locations, latitudes, or time.

One empirical means for focusing the choice of slope values is the body of literature documenting decline in species richness accompanying area reduction. J.M. Diamond termed this process “relaxation.” A number of studies, for example, have examined the relaxation in the species of mammals that may have occurred on nature reserves, both in North America and in Africa. The results of these studies clearly illustrate the difficulty in choosing a slope of the species–area relationship. For African savanna reserves, R. East has shown that estimates of species loss accompanying a 100-fold reduction in area vary from about 40% to more than 90%, depending on the required minimum viable population size (i.e., the population size that ensures persistence with a certain probability for a certain length of time). W.D. Newmark has shown that similar high variability exists for western North American national parks.

At least three potential reasons underlie the poor predictability generally seen in studies of relaxation. The first two reasons, the presence of statistical or sampling errors and the lack of sufficient time since area reduction took place to allow full relaxation, could be addressed by careful experimentation. The protocol is to document the species richness of a relatively large area, reduce the area, and then document the species richness of the reduced area. Unfortunately, most of these kinds of experiments have been carried out at such a small scale that their general value at the scale of typical nature conservation efforts is questionable. Slope values derived from these experiments are, therefore, not likely to be of much practical value. A few reasonably large scale experiments in area reduction have been undertaken, most notably The Minimum Critical Size of Ecosystem project of D.H. Janzen, T.E. Lovejoy, R.O. Bierregaard, and others. These relatively large scale experiments suggest that the species–area relationship alone does not predict species loss particularly well. Slope values derived from these experiments, therefore, also are not likely to be of much practical value. The third reason, lack of the autecological (i.e., species-specific ecological) information needed to infer that the loss of species is attributable directly to relaxation, cannot be addressed as readily by experimentation.

Recall that one of the assumptions necessary to predict loss of species accompanying area reduction was that the loss of species is a direct consequence only of area reduction. Loss of species actually may occur only as an indirect consequence of area, because of some factor that happens to be correlated with area reduction, such as level of disturbance, complexity of habitat structure, or – probably most importantly – fragmentation. It seems clear that in virtually all real-world cases, area reduction is likely to be accompanied by fragmentation. That

is, one relatively large area is not likely to be reduced to a single relatively small area, but rather to an archipelago of relatively small fragments. For example, Simberloff (1992) has shown that fragmentation effects, as well as size-dependent habitat changes, are at least as important as area reduction in predicting species loss in the relatively large scale experiments mentioned previously. It has been known for quite some time, at least since the pioneering work of N.W. Moore and others, that fragmentation can have adverse effects on organisms, independent of the effects of area reduction. The species–area relationship predicts that each of the fragments will support fewer species than the original area, but it alone cannot predict the cumulative number of species in the entire archipelago of fragments. As D. Simberloff and L.G. Abele have clearly shown, we also must know the degree of overlap in the species compositions of the fragments. If, for example, the compositions of the fragments were identical, then the archipelago would support fewer species than the original area. If, however, the species compositions of the fragments did not overlap at all, then the archipelago could support as many – or, potentially, even more – species than the original area. Assuming, realistically, that compositions overlap to an intermediate degree, calculating the loss of species by the method we have just illustrated could yield either an underestimate, if many species were confined to but a small subset of fragments, or an overestimate, if they were not. Fragmentation, therefore, adds more uncertainty – the degree of overlap in species compositions – to any prediction of the loss of species accompanying area reduction. We could predict the degree of overlap in the species compositions of fragments better if we had detailed information on the habitat requirements and minimum viable population sizes of individual species and on spatial variation in species richness, but as D. Simberloff and others have shown, such information is notoriously difficult to obtain and, therefore, is in very short supply.

Recently, a method has been suggested by Harte and co-workers whereby the slope value for species–area relationships among fragments might be obtained more easily. This method is based on the idea of self-similarity that we discussed in Self-similarity and the Power-Function Model of the Species-area Relationship. Essentially, the method requires only measurement of the degree to which species lists in separated, small, censused patches overlap as a function of the distance between patches and the area of the patches. Self-similarity, then, allows translation of the resulting slope value across scales, so that censusing of prohibitively large areas or obtaining extensive autecological information becomes, in theory, unnecessary. A.P. Kinzig and J. Harte have also developed a procedure for estimating species loss from habitat reduction that derives from the assumption of self-similarity and from examining the relationship between the number of endemic species and area, an endemics–area relationship (EAR). In the examples examined thus far, the estimated species loss from area reduction is less using Kinzig and Harte’s EAR approach than from the traditional approach based on the species–area relationship outlined above. Whether these approaches for estimating species–area slopes and calculating species loss will lead to yet another dead end remains to be determined but will depend on how reasonable it is to assume self-similarity over a range of spatial scales.

Slowing the Loss of Species

In the previous section Loss of Species from Area Reduction, we explored what the species–area relationship was able to tell us about species loss accompanying area reduction. In this section, we shall explore what the relationship can tell us about slowing that loss. In doing so, we shall treat area reduction with concomitant loss of species as an accomplished fact and concern ourselves solely with maximizing the remaining species richness. We shall, also, focus on maximizing species richness by the judicious choice, or design, of nature reserves.

The serious study of the relationship between the species–area relationship and the design of nature reserves began in the mid-1970s. At that time, several papers by J. Terborgh, J.M. Diamond, E.O. Wilson, E. Willis, and others came out more or less simultaneously highlighting the overarching importance of largeness of nature reserves. Some of these papers further maintained that the species–area relationship indicates that nature reserves should be subdivided as little as possible, that is, a single intact reserve of a certain area will support more species than a series of individually smaller reserves that are cumulative of the same area. Diamond, for example, said “many species that would have a good chance of surviving in a single large reserve would have their survival chances reduced if the same area were apportioned among several smaller reserves.” The basic problem with these ostensibly reasonable proposals – call them largeness and singularity – is that they may be too simplistic for real-world conservation challenges. They may be too simplistic because of the substantial set of assumptions that accompanies them. We shall address perhaps the most basic of these assumptions in detail. This assumption is that the importance of largeness and singularity follows directly from the species–area relationship.

Most of the early papers based their arguments for largeness and singularity on MacArthur and Wilson’s theory of island biogeography. This theory of island biogeography takes a dynamic view of the maintenance of species richness on islands, as a balance between colonization and extinction. The resulting species richness, therefore, is considered an equilibrium number of species. If relatively large areas support relatively large populations, then relatively large areas also should have relatively low extinction rates and, consequently, support relatively high equilibrium numbers of species. Accordingly, any subdivision of a relatively large area essentially creates smaller areas, each with higher extinction rates, so that the equilibrium number of species on each of the areas necessarily will fall (relaxation). The early papers also made a variety of proposals to enhance colonization, reflecting the potential importance of clustering and corridors and of shape, but we shall not address these proposals.

Almost immediately, the arguments for the overarching importance of largeness and singularity were challenged. Simberloff and Abele showed that the species–area relationship did not unambiguously favor a single intact reserve over an archipelago of smaller reserves. For example, if one assumes a power-function model of the species–area relationship ($S = cA^z$) and that $A_{\text{small}} = A_{\text{large}}/2$, then the number of species in the large reserve is $s_{\text{large}} = c(A_{\text{large}})^z = c(2A_{\text{small}})^z = 1.2s_{\text{small}}$, (Figure 4). This equation could yield S_{large}

$<2S_{\text{small}}$ in a variety of realistic circumstances. Subsequently, R.W. Rafe elaborated the mathematical underpinnings of the comparison of the relative abilities of a single large reserve (SLR) and two reserves of half the area (THR) to support species. R.W. Rafe, A.J. Higgs, M.B. Usher, and others clearly illustrated that the proportional overlap of species between the smaller reserves is a critical issue. In essence, the greater the overlap, the more an SLR is favored, and vice versa. The relevant, and critical, information necessary to predict the amount of overlap is mostly lacking, a fact mentioned earlier by Simberloff and Abele in response to criticisms of their analysis.

By the early 1980s, the controversy over choice of nature reserves had evolved into the single-large-or-several-small (SLOSS) debate. O. Järvinen, D. Simberloff, L.G. Abele, and others emphasized, once again, that the species–area relationship – or the underlying island biogeographic theory, for that matter – did not unambiguously favor a single intact reserve over an archipelago of smaller reserves. That some species might need relatively large areas for their continued well-being, whereas others could thrive in, or actually required, certain relatively small areas, had become well established in the ecological literature, beginning with the early work of J. Terborgh, R.T.T. Foreman, and others, so their proposal should not have been very controversial. This was not the case, however, and the debate continued. In 1986, M.E. Soulé and D. Simberloff gave the SLOSS debate the last rites: The SLOSS debate is no longer an issue in the discussion about the optimal size of nature reserves. Yet, rumors of the death of the SLOSS debate were greatly exaggerated, for it continued beyond the mid 1980s – briefly mutating into the single-large-or-plentifully-patchy (SLOPP) debate of M.P. Gilpin in the late 1980s – right up to the present. M.E. Soule and D. Simberloff suggested that the truly important remaining question was “the dynamics of species extinction after the reserves are set up and surrounded by habitat modified by human activities,” as had A.J. Kushlan, H. Picton, and others nearly a decade earlier. Clearly, this statement implies that too much emphasis had been placed on area (the extinction side of island biogeography) and too little on isolation (the colonization side of island biogeography). It also implies that relatively small fragments may have its worth despite their small sizes. Relatively small fragments often are not simply random samples of larger habitat units, but rather may represent special places that have been left either inadvertently or purposely. For example, R.T.T. Forman, I. Hanski, E.D. McCoy, and others have shown that relatively small fragments could harbor unusually high population densities of species or disproportionate representations of rare species. Finally, this statement implies that fragmentation cannot proceed indefinitely without severe consequences. Simberloff, for example, has pointed out that “thousands of small fragments, with large aggregate area, will not be expected to allow conservation of many species.” If this question – about the dynamics of species extinction – is indeed the only important one remaining, then the information needed to slow the loss of species accompanying area reduction largely is the same information that is needed to predict the loss of species in the first place. For example, J.G. Dony, M.E. Soulé, D. Simberloff, and others have recommended identifying target species, determining their minimum viable population sizes (MVPs), and then using known

densities to estimate needed area. Unfortunately, even if sound MVPs could be calculated for several target species in a location, the areas required to support those population sizes are likely to be poorly known, if known at all. This lack of information also plagued earlier proposals for estimating needed area, such as E.D. McCoy’s minimum refuge area, T.E. Lovejoy and D.C. Oren’s minimum critical size, and S.T.A. Pickett and J.N. Thompson’s minimum dynamic area.

How Incidence Functions and Nestedness Fit In

Recall that the SLOSS debate was generated largely by one of the early nature reserve design principles: a single intact reserve of a certain area will support more species than a series of individually smaller reserves that are cumulative of the same area. For this principle to apply universally, the minimal assumptions are that the habitats included on areas of different sizes are more or less uniform, that the population densities of species on areas of different sizes are similar, and that the process of relaxation largely is deterministic. Subsequent ecological research has made it clear that none of these assumptions always holds. However, do these assumptions hold in enough instances or to such a degree that it is possible to know the species composition of various-sized fragments with a high degree of certainty? We shall address two related methods developed to address this question.

J. Diamond developed incidence functions as a tool for determining minimum nature reserve area. The incidence function, J , equals the number of fragments (islands) of a certain size harboring a certain species divided by the total number of fragments of the same size. Supposedly, the higher the value of J at a particular size, the higher the probability that the species can persist in fragments of that size. E.F. Connor, D. Simberloff, M. Williamson, and others questioned the validity of these conclusions, but, if they do have any validity, even in a general way, then certain patterns of incidence functions could indicate that species disappear from increasingly fragmented habitats in a predictable manner.

B.D. Patterson and W. Atmar developed a sophisticated extension of incidence functions, the nestedness of species’ geographical distribution. Species’ distributions are nested when the species on the most species-poor (and, likely, smallest) fragment comprise a subset of those on the next most species-poor fragment, which, in turn, comprise a subset of those on the next most species-poor fragment, and so on. K.B. Jones and co-workers supplied the first explicit evidence for nested distributions in the mid-1980s, although implicit evidence can be found in papers by N.W. Moore, M.D. Hooper, R.T.T. Foreman, and others a decade earlier. Jones and co-workers attributed the pattern to selective extinctions in the absence of colonizations, as have most subsequent authors, although D.T. Bolger, M.V. Lomolino, and others have shown that the pattern actually can result from a number of causes. Nestedness could have important implications for nature reserve design. If the species on an archipelago of habitat fragments were a perfect subset of the species in a single large unit of habitat, then the archipelago could never contain more species than the single large unit. Furthermore, if fragments of similar size were to harbor similar suites of species, because

species loss with area reduction is deterministic, then the archipelago must contain fewer species than the single large unit. The temptation is therefore, great, to assume that simultaneously significant species–area and nested subset relationships must indicate that smaller fragments have the fewest species, but recent evidence supplied by D. Doak, E.D. McCoy, W.J. Boecklen, and others suggests that this assumption is not a good one.

Conclusions

Regardless of the reason for it, poor predictability of the effects of area reduction can stall effective decision making. A good example is the controversy over the amount of species loss accompanying tropical deforestation. For more than 30 years, ecologists have sought shortcut methods to substitute for the autecological information that is needed to improve predictability but is so difficult to obtain. To date, they have not been particularly successful. An interesting additional example that involves species–area relationships is the controversy over the amount of species loss accompanying global warming discussed by K.A. McDonald, J.H. Brown, R.W. Skaggs, W.J. Boecklen, T.E. Lawlor, and others. So, we are saddled with a seemingly unresolvable dilemma: we need more information, but we cannot afford to wait for it. Faced with this dilemma, some biologists, for example, R. East and M. Kent, have suggested that we view the species–area relationship as perhaps the best tool available for making conservation decisions and have promoted the idea of retaining large units of habitat as a matter of general course. If one is focusing solely on predicting the loss of species with area reduction and refrains from becoming overly specific, then this may be a reasonable strategy. Others, for example, C.F. Mason and E.D. McCoy, have suggested that reliance on species–area relationships may lead to undesirable conservation decisions and have promoted a “save-all-the-pieces” strategy. If one is focusing on forestalling the loss of species, then this may be a reasonable strategy (which has been termed “several little all too small” (SLATS) by E.D. McCoy and H.R. Mushinsky) for

habitats suffering from extreme area reduction and fragmentation. The SLATS strategy is likely to become increasingly relevant for most habitats, because the amount of habitat needed to allow species to persist, let alone to flourish or to evolve, appears to be much larger than humans are willing to grant.

Glossary

Apex predators Predators that have no predators of their own and are at the top of the food web.

Ecosystem services Values to humans provided by ecosystems.

Indirect effects Effects on a third species or trophic group owing to a direct interaction between two species or trophic groups. Trophic cascades are the result of the indirect effect of predator–prey interactions on a third group.

Mesopredators Predators in the middle of the food web, usually small- to medium-sized animals that are preyed on by other predators and that often benefit when apex predators decline.

Meta-analysis Method of summarizing outcomes across numerous studies by compiling measures of the effect size of treatments as, for example, measures of the differences in biomass of primary producers in the absence versus presence of predators.

Natural experiments When a change occurs in a system due to natural or anthropogenic forces, and comparisons

can be made with conditions before the change and with conditions in an environment where the change did not occur. For example, the recovery of a predator may provide a natural experiment in which conditions before and after recovery and conditions inside and outside the recovery area are compared.

Omnivory A consumer that feeds on many types of prey including, for example, a diet of plant and animal sources.

Regime shifts Dramatic changes in an ecosystem from one distinct state to another distinct state. Regime shifts are abrupt and often difficult to reverse.

Resource facilitation Activity of one species promoting the availability of resources for another species.

Trophic cascades The effects of predatory feeding on prey that propagate down more than one link in a food web.

Trophic cascades cause inverse patterns in the abundance or biomass of trophic groups at successive levels of a food web.

Trophic downgrading Ecological and environmental consequences associated with losses of apex predators from ecosystems.

Introduction: The Far-Reaching Effects of Predation

When predators reduce prey populations, the effect can propagate, causing an increase in prey lower in the food web. This dynamic interaction is a trophic cascade. Trophic cascades cause inverse abundance or biomass patterns across more than one trophic link in a food web (Pace *et al.*, 1999). Consider a two-level food chain of primary producers and herbivores. A trophic cascade would occur if a predator were introduced that reduced the biomass of herbivores, resulting in an increased biomass of primary producers due to eased grazing (Figure 1). However, not all predator–prey interactions propagate down food webs via trophic cascades. Extensive omnivory and multiple predators and prey embedded in complex food webs blunt trophic cascades (Polis and Strong, 1996). In addition, there are many behavioral, morphological, and chemical defenses that reduce the impacts of predators. Despite this complexity, trophic cascades are observed in terrestrial, marine, and freshwater systems and may cause transitory or permanent shifts in biomass of trophic groups within ecosystems.

The earliest studies of ecosystems provided a “bottom-up” perspective on the control of productivity. Physical–chemical forcing factors such as sunlight and nutrient availability controlled photosynthesis, and the resulting primary production determined production of secondary consumers via transfers of energy up the food web. Hairston, Smith, and Slobodkin (1960), in a famous paper, challenged this perspective by arguing that predators limited herbivores, reducing herbivory, with the consequence of a “green” world of lightly grazed

plants. Although the Hairston, Smith, and Slobodkin argument was controversial, their paper was among the first descriptions of predatory “top-down” regulation. Paine (1980) first described the propagating effects of predators in the marine intertidal zone as “cascading alterations in structure.”

Figure 1 Two simple food chains depicting the impact of a trophic cascade. In the two-level food chain, herbivore grazing limits primary producers. Adding a predator to create a three-level food chain causes a decline in herbivores, which leads to reduced grazing and an increase in primary producers.

Terrestrial researchers noted inverse patterns of biomass in some food chains of plants, rodents, and predators, especially those in high northern latitudes (e.g., Oksanen *et al.*, 1981). In freshwater systems, researchers observed that shifts in top fish predators caused strong cascading changes in prey fishes as well as in invertebrates, with consequences for primary producers (Hrbáček *et al.*, 1961; Power, 1990). Carpenter *et al.* (1985), drawing on examples from lakes, popularized the concept of trophic cascades and the impacts of apex predators that could transfer all the way down the food web.

Subsequent research has focused on the occurrence and relative importance of trophic cascades in a variety of ecosystems, with a particular interest in whether cascades influence primary producers. The term “trophic cascade” applies broadly across population, community, and ecosystem levels of organization. Hence, a species might be influenced by a trophic cascade with consequent effects on its abundance. Because of elk grazing, aspen trees (*Populus tremuloides*) were rare when wolves (*Canis lupus*) were absent from Yellowstone National Park (USA) (Ripple *et al.*, 2010). When wolves were reintroduced, aspen increased to abundances similar to levels observed before the extirpation of wolves. The distribution and abundance of the aspen population are significantly driven by a trophic cascade. The term “trophic cascade” is also used in the context of communities. Trophic cascades may affect feeding groups or entire trophic levels. Some researchers have advocated labeling this pattern of top-down regulation as “community cascades,” restricting the use of the term “trophic cascades” to specific cases in which the impact manifests as changes in primary production (Polis *et al.*, 2000). In this view, cascades are important only if they affect how “green” (i.e., productive) or “brown” (i.e., unproductive), in the case of terrestrial vegetation, an ecosystem appears (Polis *et al.*, 2000). In practice, the term carries a broader if more diffuse application.

Trophic cascades are by definition dynamic. The outcomes of trophic cascades may result in a relatively permanent change in the structure of food webs and lead to distinct differences in the biomass of trophic levels, as indicated in **Figure 1**. Ecosystems are complex, however, with temporal and spatial heterogeneity in population processes and trophic interactions. Trophic cascades may induce compensatory responses and result in variability in system components rather than permanent change. Consider a lake food web with four trophic levels: piscivorous fish, planktivorous fish and invertebrates, zooplankton herbivores, and phytoplankton. Variable recruitment of the top predators may lead to enhanced periods of predation pressure by planktivores on zooplankton. This occurs when dominant, older age classes of the piscivores die off, and planktivores (including young, planktivorous-feeding life stages of the piscivore) recruit in a pulse. These changes create a period of strong planktivory with cascading consequences that ameliorate as the piscivore population re-establishes (Post *et al.*, 1997). Thus, trophic cascades are one of many forces leading to variability in food webs. This dynamical aspect of trophic cascades is probably widespread and counters the simple view that cascades are significant regulatory forces only when effects cause community-level alterations in biomass or productivity that propagate to primary producers.

Trophic Cascade Examples: Wet and Dry

Trophic cascades occur in terrestrial and aquatic ecosystems. The earliest examples of trophic cascades were found in coastal water and freshwater systems. Strong (1992) argued that cascades were “all wet” – meaning confined largely to aquatic systems – because of greater potential in aquatic ecosystems for “runaway” consumption of primary producers by herbivores. In contrast, terrestrial plants resist excess consumption through a variety of defenses. However, trophic cascades occur in a spectrum of ecosystems including many terrestrial environments (Pace *et al.*, 1999; Estes *et al.*, 2011). Further, many aquatic primary producers are also defended and resist herbivory. At this stage (*see* Trophic Cascades: When, Where, How Much?) it is not clear whether trophic cascades are more common in aquatic systems than in terrestrial ones, but they are certainly not “all wet.”

Some of the best evidence for the importance of trophic cascades comes from the recovery of apex predators. These recoveries have provided researchers with the opportunity to study and understand the impacts of cascades, as in the following two examples.

Sea otters (*Enhydra lutris*) drive a well-understood trophic cascade in the coastal waters of northwestern North America. Urchins (echinoderms) eat kelp, but otters eat urchins, and through predatory control of urchin populations, kelp forests can flourish. This cascade was first discovered when otters were protected from hunting, allowing their populations to recover from near-extinction (Estes and Palmisano, 1974). Subsequent site-specific reductions of otters due to disease or predation have led to a reversal of otter control on urchins. When otters decline to low levels, urchin populations increase unchecked and drive the loss of kelp beds, creating barren bottom areas. As a consequence, these coastal ecosystems exhibit alternate states of kelp forest and urchin barrens due to effects that emanate from otter predation. Regime shifts between alternate states as evidenced in the otter–urchin–kelp interaction are a significant outcome of changes in trophic cascades.

Like otters, wolves were driven to near-extinction throughout much of their range due to overhunting, but under protective laws, wolves are recovering in many areas. The return of wolves to the Banff region of the Canadian Rocky Mountains provides evidence of trophic cascades and other indirect effects of wolf predation (Hebblewhite *et al.*, 2005). Where wolves re-established, the population density, female survival, and recruitment of elk were all negatively impacted. In the absence of wolves, aspen and willow browsing by elk was greater and recruitment of these trees was near zero (**Figure 2**). This effect on tree recruitment is the same as described for Yellowstone Park. Interestingly, the higher elk populations in areas of Banff not used by wolves were also associated with lower populations of beavers and song birds due to reductions in riparian vegetation caused by elk grazing (**Figure 2**). This is a case of an indirect effect of predators on other animal populations through a trophic cascade that changes habitat suitability and biodiversity.

The wolf and sea otter recoveries also illustrate the difficulty of studying trophic cascades that originate from top predators. Natural experiments as opposed to controlled manipulations provide the evidence supporting conclusions

Figure 2 Trophic interactions for the Banff National Park area of Canada depicting the trophic cascade of wolves–elk–aspen/willow. Solid lines are direct predator–prey interactions, with +/– indicating the direction of the effect. Dashed lines represent indirect effects; for example, wolves have a positive indirect effect on aspen and willows, whereas elk have negative indirect effects on birds and beavers. Reproduced from Hebblewhite M, White CA, Nielvelt CG, *et al.* (2005) Human activity mediates a trophic cascade caused by wolves. *Ecology* 86: 2135–2144, with permission from ESA.

about trophic cascades in these cases. Research to establish these impacts was carried out over large areas, took many years, and required comparison among systems. To encompass and evaluate large predators with extensive ranges, researchers must often consider large spatial areas and long time scales. Many predators are also difficult to manipulate and do not fit within typical experimental units (e.g., cage enclosures). The study and understanding of predator impacts has lagged partly because of these difficulties and partly because top predators are absent and, unlike otters and wolves, have not recovered in their native ecosystems.

Shifts caused by predator introductions do not always result in a return to a previous state as in the wolf and otter cases. Novel predators may cause trophic cascades that move an ecosystem far from the “native” condition. On Christmas Island south of Java, red land crab (*Gecarcoidea natalis*) was an extremely abundant herbivore that suppressed forest understory plants. Explosive population growth of an invasive ant species (*Anoplolepis gracilipes*) wiped out the crabs over much of the island, allowing plant recruitment and the development of a lush forest understory (O’Dowd *et al.*, 2003). In locales where crabs remain abundant the forest floor is open with few saplings and little leaf litter, but where the island is dominated by ants, there is much higher plant biomass and richer plant diversity. Ants also altered the canopy by developing associations with scale insects collectively promoting the growth of molds, leading to canopy dieback. The ecosystem under ant dominance is now completely different (O’Dowd *et al.*, 2003).

Trophic Cascades: When, Where, How Much?

Are trophic cascades an ecological curiosity or a phenomenon of widespread importance, common in many systems? When

and where do trophic cascades occur, and what factors are related to the strength of trophic cascades? These questions address the generality and significance of trophic cascades. Ecologists have posed many ideas about characteristics of food webs, diversity of producers and consumers, metabolic attributes, key traits of consumers, and other features that could influence the propensity and strength of cascades. One way to address these questions is by synthesizing the results of many studies through the techniques of meta-analysis. A common metric for assessing trophic cascades is the biomass of autotrophs (primary producers) with and without top predators. The log of the ratio of autotrophic biomass in the presence to absence of predators was compared for over 100 studies that included a wide diversity of methodologies and ecological characteristics (Shurin *et al.*, 2002; Borer *et al.*, 2005). Trophic cascades as measured by the log ratio are stronger in some types of systems (e.g., the marine benthos) and the strength of cascades is related to the metabolic efficiency of herbivores and predators. For example, trophic cascades are stronger when herbivores have a high metabolic efficiency (e.g., ectothermic organisms), allowing enhanced conversion of the autotrophic food to growth. Many other factors such as diversity of consumers or producers within a trophic group or rates of primary production had little influence when considered across a large suite of studies (Borer *et al.*, 2005). These types of synthetic studies also indicate limitations in the data available for meta-analysis. For example, there are relatively few studies from terrestrial systems and even fewer studies that have manipulated terrestrial endothermic predators (Borer *et al.*, 2005).

The generalities drawn from meta-analyses need cautious consideration because, in part, results are analyzed for studies that use a variety of methodologies and experimental scales (Whittaker, 2010). In lakes, for example, the patterns of trophic cascades across gradients of nutrient enrichment and primary production differ from the results of meta-analysis based on many different types of systems. Whole lake manipulations done with consistent methods over the same temporal scale illustrate that trophic cascades are stronger when nutrient loading (additions of nitrogen and phosphorus) and hence potential primary production is greater (Carpenter *et al.*, 2001). Lakes responded to increased nutrient loading with large increases in phytoplankton biomass when plantivores and small grazers were the dominant food web constituents (Figure 3). In contrast, in lakes dominated by piscivores and large zooplankton grazers, there was a limited increase in phytoplankton primary production and biomass across a range of nutrient loads (Figure 3). This result contrasts with the lack of any effect of primary production on the strength of trophic cascades found in meta-analyses (Borer *et al.*, 2005). Stronger trophic cascades in more productive ecosystems may be particular to lakes, or alternatively, data across many types of ecosystems may be too limited to have strong confidence in the results of meta-analyses.

The ecological features that promote or inhibit cascades remain an open question because: (1) methods in ecological research are variable among studies, making comparisons difficult; (2) trophic cascade studies typically require large spatial and temporal scales and studies at these scales are less common; and (3) the number of case studies is limited,

Figure 3 Trophic cascades in lakes affect the response of phytoplankton biomass measured as chlorophyll to increased nutrient loading measured as phosphorus input. Each point represents a different year for the two lakes – one with planktivorous fish as top predators and one with piscivorous fish as top predators. In the planktivore lake, herbivores were smaller, less effective grazers and phytoplankton biomass was greater at the given nutrient load. In the piscivore lake, herbivores were larger, more effective grazers and phytoplankton biomass was lower. Reproduced with permission from Terborgh J and Estes JA (eds.) (2010) *Trophic Cascades: Predators, Prey and the Changing Dynamics of Nature*. Washington, DC: Island Press.

especially those that consider trophic cascades under varying ecological conditions, such as differences in nutrient loading. Ecologists can still profitably argue about whether trophic cascades are more likely in terrestrial versus aquatic systems, whether predator-induced switches to efficient herbivores are critical for driving cascades to primary producers, and how the characteristics and diversity of plant communities influence cascades. Simple answers may not emerge but instead may depend on the organisms and the context of particular ecosystems. Nevertheless, a recent volume that includes many case studies points to the importance of predators and cascading trophic interactions in ecosystems throughout the biosphere (Terborgh and Estes, 2010).

Consequences of Trophic Cascades

The cascading impacts of predators are not just about whether ecosystems have more or less primary production but include many other effects. Here a distinction is needed between direct predatory effects and the indirect effects inherent in trophic cascades. Recall that, by definition, beyond the direct effect of predator on prey, trophic cascades require an indirect effect at lower levels of the food web. Other indirect consequences result from the shifts in biomass and organism abundances induced by trophic cascades. These include consequences for processes related to biogeochemical cycling, crosshabitat linkages, and ecosystem services. Indeed, given the impacts of predators on phenomena such as fire frequency and disease (Estes *et al.*, 2011), it is likely that there are many other collateral consequences of trophic cascades yet to be discovered.

Biogeochemical processes are largely driven by the unique metabolic capabilities of microorganisms in concert with

Figure 4 A crosshabitat trophic cascade of fish–dragonflies–insects that affects the pollination of riparian plants. Solid lines indicate the direct effects of trophic interactions. Dashed lines indicate the indirect effects of fish. Modified from Knight TM, McCoy MW, Chase JM, McCoy KA, and Holt RD (2005) Trophic cascades across ecosystems. *Nature* 437, 880–884, with permission from nature Publishing Group.

primary producers that utilize nutrients and generate the organic matter fueling elemental cycles. Trophic cascades driven by predatory animals can determine patterns of nutrient recycling and even the net direction of biogeochemical fluxes. For example, the presence or absence of piscivorous, large-mouth bass (*Micropterus salmoides*) in experimental lakes fertilized with nutrients was the key to whether lakes were net sources or sinks of CO₂ (Schindler *et al.*, 1997). How did bass influence a physical–chemical process such as the flux of a gas between the atmosphere and a lake? In the absence of bass, planktivorous fish dominated, suppressing large-bodied zooplankton grazers and promoting greater phytoplankton production and hence uptake of CO₂. Under these conditions, lakes became undersaturated in CO₂ with a resultant movement of CO₂ from the atmosphere to the lake. In other experimental lakes with bass, zooplankton exerted greater control of phytoplankton production. Phytoplankton took up less CO₂ and in combination with the microbial respiration of terrestrial organic matter more CO₂ was produced than consumed. The bass-dominated lakes were net sources of CO₂ to the atmosphere.

Trophic cascades can spill across habitat boundaries via the movement, life histories, and predatory impacts of organisms. Dragonflies deposit their eggs in water and the larvae grow in the aquatic system, where they are a favored prey item of fish. Knight *et al.* (2005) compared ponds with and without fish and found many more dragonfly larvae in fishless ponds. This predator–prey interaction caused a trophic cascade that affected the pollination of riparian plants (Figure 4). Around the fishless ponds, dragonfly adults were more abundant, they preyed on pollinator insects, and as a consequence, there were fewer pollinator visits to plants such as St John's wort (*Hypericum fasciculatum*). The opposite conditions prevailed in and around ponds with fish – dragonfly larvae and adults were fewer, flies and bees were more abundant, and pollinator visits to *Hypericum* plants were more frequent. The trophic cascade

in this case was crosshabitat with pollination influenced by dragonflies as both prey and predators.

Humans harvest natural resources and receive many benefits from ecosystems. Resources and benefits that result from the operation of ecosystems are known as ecosystem services. Alterations of trophic cascades can change the services provided by ecosystems with important impacts on human welfare. For several centuries, the continental shelf off Nova Scotia, Canada, supported a highly productive cod (*Gadus morhua*) fishery. The cod population collapsed due to overfishing in the early 1990s. The loss of cod altered the system via a shift in cascading trophic interactions (Frank *et al.*, 2005). When cod collapsed, small pelagic fishes, crabs, and shrimp increased, zooplankton declined, and phytoplankton increased. Interestingly, this shift was observed despite the physical dynamics and the large food web complexity of the marine environment, which might be expected to obscure strong trophic cascades.

The collapse of cod had great economic impact, but the rise of the pelagic fishes and crustaceans led to a new fishery that currently produces a higher economic value than the prior cod fishery (Frank *et al.*, 2005). In this case, cascading trophic interactions changed with the resulting impact that the former ecosystem service was lost but a new service of greater value emerged. Although this may seem a positive outcome, the decline of cod had devastating social effects that extended beyond fishing. In most cases where ecosystem services are lost, they are expensive or in some cases impossible to replace. For example, in an agricultural region of south central Texas, USA, Brazilian free-tailed bats (*Tadarida brasiliensis*) prey on agricultural pests of cotton, reducing crop damage – a trophic cascade (Cleveland *et al.*, 2006). Brazilian free-tailed bats have a positive effect on both conventional and genetically modified cotton, reducing the number of sprayings of pesticides and hence costs to growers (Federico *et al.*, 2008). Other species of bats with similar impacts on agricultural systems are currently in decline in North America due to emerging diseases (e.g., a fungal infection of hibernating bats) and other factors (e.g., mortality from the growing use of wind turbines). The estimated value of bats in the US as agents of pest control may be over a billion of dollars (Boyles *et al.*, 2011). Loss of trophic cascades involving bats, insect pests, and crop plants would invoke significant costs due to lost production and increased expenses of treatment with pesticides.

Conserving Not Only the Big and Fierce but Also the Small and Timid

Colinvaux (1978) wrote a book explaining the general concepts of ecology including a problem posed in the book's title, "Why big fierce animals are rare (...)." The answer to this problem relates to the efficiencies of ecological food chains. You are more likely to encounter a squirrel in your backyard than a lion because squirrels feed lower on the food chain, mainly on a variety of plentiful plant items. Lions feed on vertebrate prey, which they must hunt, attack, and kill. Lions must pay a large cost in acquiring food, and there is a greater limitation of prey (fewer wildebeest than nuts). Energy limitation explains the rarity of large predators.

But predators are also rare because they have been persecuted by humans. In every ecosystem of the earth, apex predators have been killed because they either compete with or are a danger to humans. Apex predators are also targeted for food, for fur, and as trophies. Consequently, there is a second, more insidious answer to Colinvaux's problem. Large, fierce predators are rare because humans have diminished or totally eliminated their populations. The nexus of effects of this loss of top or apex predators has been recently dubbed "trophic downgrading" (Estes *et al.*, 2011). Generally, trophic downgrading of ecological systems has led to a loss of top-down regulation with changes in the abundance of consumers susceptible to predation as well as many consequences related to a lack of predators. For example, in the absence of wolves, abundant deer populations impact riparian vegetation, causing erosion and loss of shoreline integrity on stream banks (Ripple *et al.*, 2010). The global diminishment of the "big and fierce" has led to impoverished ecological interactions, some of which are now lost forever due to permanent predator extinctions.

Another consequence of the loss of large, apex predators is that smaller predators lower in the food web have become more abundant and have assumed in many systems the role of apex predators, a phenomenon known as mesopredator release. These mesopredators include a variety of species. In terrestrial environments they are often small- to medium-sized vertebrates. In aquatic systems they are either the younger and smaller age classes of the apex predator fishes or medium-sized fish species that were previously in the middle of the food web. Mesopredator release appears responsible for many ongoing changes in ecological systems. For example, the loss of large predators, including lions and panthers, has released olive baboons (*Papio anubis*) in Ghana, West Africa (Brashares *et al.*, 2010). In many locales, baboons are now hyperabundant. Baboons may shift to a more carnivorous diet when released, and there are correlations between increases in baboons and declines in numbers of small primates, in numbers of small ungulates, and in bird nesting success (Brashares *et al.*, 2010). In addition, marauding troops of baboons increasingly invade homes and destroy crops. This is one of many examples where mesopredator release has resulted in some species becoming abundant with attendant losses of biodiversity and negative impacts on humans (Prugh *et al.*, 2009).

Sustaining predators and restoring trophic cascades are important goals for conservation and restoration. Apex predators are a key target as conserving these species may also contribute to sustaining many attributes of the ecosystems that support them. For example, apex predators may promote species richness through trophic cascades and a variety of other mechanisms such as resource facilitation as when predators make carrion available for scavengers (Sergio *et al.*, 2008). Apex predators are also indicators. Where present, they are often associated with high biodiversity and greater ecosystem complexity. The absence of predators can indicate anthropogenic disturbance associated with lower diversity. Finally, because apex predators require large areas, their effective conservation can lead to the creation of large reserves and promote the establishment of corridors between conserved areas for predator movement (Sergio *et al.*, 2008).

With the perspective of trophic cascades, it is also clear that some intermediate species in the food web are necessary targets for conservation and restoration. An example is the European wild rabbit (*Oryctolagus cuniculus*). Within its native range, European rabbits are an important grazer and a key prey for many vertebrate predators, including two endangered species: the Iberian lynx (*Lynx pardinus*) and the Spanish imperial eagle (*Aquila adalberti*; Lees and Bell, 2008). Although the European rabbit is quite fecund and capable of rapid growth, populations are diminished in Iberia because of habitat loss, human hunting pressure, diseases, and predation. Hence, conservation of apex predators such as lynx depends, at least in part, on rabbit conservation, and rabbits are being restocked in areas of Spain and Portugal to promote predators and reestablish native trophic cascades. Maintaining the big and fierce also requires the small and timid.

Conclusion and Prospects

Trophic cascades are a feature of many ecological systems. Although cascades are now documented for many locales, the ecological rules that promote cascades are incompletely understood. This means, as in many areas of ecology, there is a need for theory that can better explain trophic cascades. The addition or removal of predators particularly as the result of human activity often makes trophic cascades apparent. A frontier research area is to gain a greater appreciation for the many consequences of trophic cascades, particularly those that impact ecosystem services. Another frontier is the restoration of lost trophic cascades. Trophic cascades should be partially restorable with the return of large apex predators to systems where they have been extirpated. Restoring and conserving these predators in a world of changing climate, growing human populations, and increased pressure on natural systems will require new knowledge about ecological systems, better surveillance of predator populations, and a willingness to manage ecosystems to promote predator survival. The alternative is a world of trophic downgrading and cascades lost.

Glossary

Basal species A species that eats no other species.

Ecological transfer efficiency The ratio of energy ingested by a population's predators to energy ingested by the population.

Food chain A sequential relationship of the form x_1 is eaten by x_2 which is eaten by x_3 which is eaten by ... which is eaten by x_n .

Food web A specification of which species eat which in an ecosystem.

Trophic level of a species $1 +$ a weighted average of the lengths of all food chains linking that species to basal species. Different weightings may be appropriate for addressing different questions.

Food Chains and Trophic Levels

Trophic ecology has to do with feeding relations—for instance, weasels eat mice, mice eat herbs—and is among the most basic organizing principles underlying biodiversity in natural ecosystems. One of the earliest attempts to identify ecosystem structure was based on trophic ecology, as follows. Some species in nature (mostly plants) do not eat anything; instead they utilize solar energy through photosynthesis and are called *primary producers* or *autotrophs*. Other species eat autotrophs and are called *herbivores* (Figure 1). *Carnivores* eat herbivores, *secondary carnivores* eat carnivores, *tertiary carnivores* eat secondary carnivores, and so on (Figure 1). These are, of course, highly aggregated entities: each of the categories just mentioned contains many species in any given ecosystem.

A *food chain* is a sequential relationship of the form x_1 is eaten by x_2 which is eaten by x_3 which is eaten by ... which is eaten by x_n , where the entities x_i might be individual species, or they might be aggregations such as those just defined.

Early trophic ecology (approximately the 1930s through 1970s) viewed an ecosystem as a single food chain involving the aggregated entities just defined, as depicted in Figure 1. In this view of an ecosystem, autotrophs constitute “trophic level” 1, carnivores constitute “trophic level” 2, secondary carnivores are “trophic level” 3, and so on. (I am using “scare quotes” for the term “trophic level” because there are difficulties with this particular definition, see Food Webs and Trophic Levels.) The International Biological Program (IBP) of 1964–1974 was very much organized around this concept of ecosystem structure.

The concepts of food chain and trophic level are very closely related. Thus, in the formulation sketched in Figure 1, species in the n th trophic level are linked to primary production (autotrophs) through a food chain of length $n - 1$.

There is another food chain that is very important in a great many ecosystems, namely, the one that is based on detritus. Detritus is certainly eaten by a wide variety of organisms, but it is not itself a living organism, so it cannot exactly be said to “eat” anything. However, biomass does move from living organisms into detritus as they decay after dying. If one is

concerned to follow the recycling of specific nutrients, one needs to keep track of this entire dynamic. For purely trophic studies it is generally adequate (and far simpler) to treat detritus as though it were another organism that, like an autotroph, does not eat anything. Then autotrophs and detritus together are called *basal species*, and the detritivores are lumped together with the herbivores in trophic level number 1.

The Utility of Trophic Levels

The trophic level concept has been exceptionally durable: it has been one of the basic concepts of ecology for six decades and is one of the few ecological concepts contained in the vocabulary of most educated people. The reason for this distinguished place in the scheme of things is that the concept is both simple and useful. Furthermore, it is universal: it applies to all ecosystems.

Because of this universality, trophic levels enable us to compare the role of vastly different species in vastly different systems. For instance, we can discuss and understand a lake and the surrounding forest with a common language: the forest has its vegetation and its leaf litter; the lake has its phytoplankton and its dissolved organic matter (basal species). The forest has herbivorous insects, birds, and mammals; the lake has zoo-plankton (herbivores). And so on. We can use the same language to compare these two systems with any other ecosystem anywhere in the world.

This categorical and conceptual role can be made more quantitative and detailed, revealing important similarities and important differences among systems, by adopting a *bio-energetic* viewpoint, as follows.

Biological organisms contain caloric energy, which is transferred to organisms in the next step up a food chain: herbivores gain energy from consuming basal species, carnivores gain energy by consuming herbivores, and so forth. Each organism, or set of organisms such as a trophic level, *produces* energy at a certain rate. This is the maximum rate at which the next trophic level up the food chain could in principle ingest energy.

The rate of energy production by a trophic level must necessarily be less than the rate of energy ingestion by that trophic level. First, not all energy ingested by an organism is available to be metabolized by that organism. Some of it will be lost to excretion. The ratio of metabolizable energy to ingested energy is called *assimilation efficiency* and is typically about 0.45 for herbivores and 0.85 for carnivores. Of the metabolizable energy, some is lost to respiration, being used up by the organism to carry out its various activities and also simply to live, and the remainder is available for the production of new tissue, which can in principle be consumed by the next trophic level. The ratio of energy production to metabolizable energy is called *production efficiency* and ranges from about 0.1 to 0.4 for invertebrate ectotherms to about 0.01–0.03 for endotherms. Furthermore, not all of the energy produced at a trophic level will actually be ingested by the next higher trophic level: much of it will be missed and end up as detritus. There is no generally agreed term for this form of energy loss, nor is there a great deal of quantitative data for it.

Figure 1 The IBP conception of an ecosystem as a linear sequence of trophic levels.

The *ecological transfer efficiency* of a trophic level is the ratio of (energy ingested from that trophic level by the next highest trophic level) to (energy ingested by that trophic level). It is the product of the three efficiencies explicated in the preceding paragraph. Ecological transfer efficiency ranges from 0.001 or smaller (depending upon losses to detritus) up to a maximum of about 0.5.

It quickly becomes apparent that energy is dissipated quite rapidly as we ascend a food chain. Suppose, for example, that each ecological transfer efficiency in a food chain is 0.1, which is rather high. Then of the energy produced by basal species (primary production), one-tenth is produced by herbivores. One-tenth of that, or one-hundredth of primary production, is produced by carnivores. One-tenth of that, or one-thousandth of primary production, is produced by secondary carnivores, and so on up the food chain. Less and less energy is available to higher trophic levels as we move up a food chain. One can visualize this phenomenon as a “pyramid of production” for a food chain (**Figure 2**).

This geometrically decreasing production as we move up a food chain, hence the rapidly decreasing available energy flow for the next higher trophic level, has been offered as one possible explanation for the apparently limited number of trophic levels in natural systems. Eventually, as we move up a food chain, the small fraction of primary production available to a putative next highest trophic level simply will not be enough to support a viable biological population.

The pyramid of production is an inescapable consequence of the dissipative processes, sketched above, that lead to ecological transfer efficiencies less than 1. There are a couple of similar “pyramids” that, while not universal in this way, are fairly typical of trophic levels. They follow from the circumstance that, for the most part, predators tend to be larger than their prey. For a predator to be larger (hence also faster and stronger) than its prey greatly facilitates the capture and consumption of prey.

Thus, as we move to higher trophic levels, we will, generally speaking, see larger animals. And yet, moving to higher trophic levels, these larger animals need to live on smaller energy production from the next trophic level down. As a result, there will usually be fewer animals at higher trophic levels. This “pyramid of numbers” is frequently, though not necessarily always, observed.

Figure 2 The pyramid of production in an ecosystem. The width of each layer is proportional to the rate of production of biomass in the corresponding trophic level. Because energy is dissipated in each transfer from one trophic level to the next, production decreases at an approximately geometric rate as trophic level increases.

An obvious exception to the pyramid of numbers emerges if we treat parasites and parasitoids as “predators”; they are almost always smaller than their “prey.” Even though parasitism is tremendously widespread in nature, these are not really trophic relationships, and so most trophic studies do not include parasites or parasitoids.

What about total biomass [= (number of animals) × (weight of each animal)] at each trophic level? The number of animals tends to decrease as trophic level increases, while the weight of each animal tends to increase. The result is equivocal. Particularly in aquatic systems, where very small organisms at low trophic levels have very rapid rates of biomass turnover and can be grazed to quite low levels, one frequently (but not always) sees “inverted pyramids” of biomass, with more biomass at higher trophic levels. But terrestrial systems typically (though by no means always) display pyramids of biomass, with less biomass at higher trophic levels.

There are exceptions to this scheme, but they prove the rule; that is, they make sense in terms of the ideas underlying the scheme. For instance, some of the very largest animals, such as elephants and big ungulates, are herbivores. These animals are so large that they could not possibly range far enough to live by eating, say, lions. The only way to get a high enough energy density to support such large animals is by feeding directly on plants.

Just as energy propagates upward through food chains, so may chemical substances contained in organisms. This

becomes particularly interesting when toxic contaminants are present. If those toxic substances are absorbed and/or ingested by animals at some trophic level, then, depending upon the rate at which they are excreted, there may be residues in the tissue consumed by higher trophic levels. Under some circumstances, the concentration of toxins may increase as trophic level increases, which is called *biomagnification*.

Food Webs and Trophic Levels

The conception of an ecosystem as a linear chain of “trophic levels” (Figure 1) is a useful starting point, but if we examine trophic relations with a higher degree of taxonomic resolution—that is, not lumping so many biological species together as we did in motivating Figure 1—we find quite a different trophic structure. A *food web* is a specification of which species eat which in an ecosystem. For instance, Figure 3 is a food web for Wytham Wood, a forest near Oxford in England. An arrow from one kind of organism to another indicates that the organisms at the head of the arrow eat the organisms at the other end.

One can detect something like “trophic levels” here (partly because of the way I chose to draw the picture), but there is certainly not a simple flow of energy through a linear sequence of levels as in Figure 1; this picture is more “webby.” For instance, we might put weasels at “trophic level” 5, because they

Figure 3 A food web for Wytham Wood, England (based on data in Varley GC (1970) The concept of energy applied to a woodland community. In: Watson A (ed.) *Animal Populations in Relation to Their Food Resources*. Oxford: Blackwell Sci).

Table 1 Food chains and trophic levels in the Wytham Wood food web of **Figure 3**

Species	Number of chains to basal species of length				Trophic level using		
	1	2	3	4	Shortest chain	Longest chain	Mean length
Insects	1	0	0	0	2	2	2.0
Winter moth	2	0	0	0	2	2	2.0
<i>Tartrix</i>	1	0	0	0	2	2	2.0

eat titmice, which eat spiders, which eat insects, which eat herbs. But weasels also eat voles and mice, which eat herbs: this would put weasels at “trophic level” 3.

We do not want to throw away the trophic level concept altogether—it is too useful for that—but in the light of more refined data such as **Figure 3**, we need to refine our concept of trophic level. In fact, there are a number of different ways that we may define the term “trophic level,” and it seems imprudent to insist that any one definition is “The Right” one. Rather, different trophic level concepts may be appropriate for different purposes.

The constant theme linking all trophic level concepts together is the idea that trophic level has to do with the lengths of food chains linking a species to basal species. We just have to bear in mind that a species will generally be linked to basals through several food chains, which might be of different lengths. For instance, there are 13 food chains that link weasels to basal species in the Wytham Wood food web of **Figure 3**. Three of these have length 2, 9 of them have length 3, and 1 of them has length 4. The relative importance assigned to these 13 food chains distinguishes several different definitions of “trophic level.” Five commonly used definitions are listed here; following discussion of these, a sixth, in a considerably different spirit, will be addressed:

- 1 + the length of the shortest food chain linking a species to some basal species.
- 1 + the length of the longest food chain linking a species to some basal species.
- 1 + the mean length of food chains linking a species to some basal species.
- 1 + the weighted mean length of food chains linking a species to some basal species, where the weighting reflects energy flow through each food chain.
- $\lambda + (\delta X_{\text{organism}} - \delta X_{\text{reference level}})/E$, where E is the average enrichment of a heavy isotope and $\delta X = [(R_{\text{sample}}/R_{\text{standard}}) - 1] \times 10^3$. Here X denotes the heavy isotope (for instance, ^{13}C , ^{15}N , or ^{34}S) and R denotes the heavy/light

ratio (for instance, $^{13}\text{C}/^{12}\text{C}$, $^{15}\text{N}/^{14}\text{N}$, or $^{34}\text{S}/^{32}\text{S}$). The trophic level of the reference level organisms is λ : this might be basal species ($\lambda = 1$), or perhaps herbivores ($\lambda = 2$).

Definition 5 requires explanation. Certain heavy isotopes are enriched relative to the light isotope in biochemical reactions. As a result, the ratio of heavy to light isotope in an organism’s tissue may bear a systematic relation to the ratio in that organism’s diet. For instance, the ratio $^{15}\text{N}/^{14}\text{N}$ appears to be enriched by $E = 3.4\text{‰}$ ($\pm 1\text{‰}$) in a wide variety of organisms. Therefore, if we know the isotope ratio for organisms at some reference trophic level, we can use Definition 5 to calculate a trophic level from measurements of the isotope ratio in other organisms. The resulting numbers, which are a weighted average over all food chains from the reference level to the organisms in question, are probably fairly close to what we would get from Definition 4. This method requires far less effort than a direct calculation of Definition 4 would; for instance, there is no need to measure dietary proportions. It does require careful calibration of isotope ratios at the reference level, including allowance for possible differences among species at that level. In practice, use of the $^{13}\text{C}/^{12}\text{C}$ ratio has not been fruitful, in part because so little ^{13}C is enriched at each trophic transfer, but as of this writing, the $^{15}\text{N}/^{14}\text{N}$ ratio appears to hold promise as a tool for trophic studies.

Table 1 shows, for each nonbasal species in the Wytham Wood food web, the frequency distribution of food chains linking that species to basals and the consequent trophic level according to Definitions 1–3. (Definitions 4 and 5 require more data than are available for the Wytham Wood food web.) For instance, depending upon the relative importance attached to the 13 food chains linking weasels to basal species, we may put weasels at trophic level 3 (shortest chain; Definition 1), 5 (longest chain; Definition 2), or 3.8 (mean length; Definition 3).

Generally speaking, one would like to use something like Definition 4, even though it means replacing the notion of

discrete trophic levels with a trophic continuum. However, calculating trophic level in this way requires a tremendous amount of data. Definition 5 may be a good surrogate, but it still requires data beyond the food web itself. One is tempted to regard Definition 3 as a reasonably good substitute, but if we are thinking energetically, then because of the dissipation of energy as we move up a food chain, the shorter chains may well be more important energetically than the longer ones, so the equal weighting of Definition 3 may be deceptive. Definition 2 is what one has in mind implicitly when one draws tidy pictures such as [Figure 3](#), but the existence of very long food chains can be deceptive. Animals that have a food chain to basals with 8, 9, or even 10 links exist, but they invariably also have chains no longer than 3 links, and these shorter chains are likely more important energetically. However, very long food chains may be particularly significant if one is concerned with biomagnification of toxin concentrations.

Another viewpoint, which ought to produce a sixth trophic level definition if it could be articulated precisely enough, emphasizes the *top-down* aspect of trophic relationships. This viewpoint, which has been put forward by S. Fretwell and L. Oksanen, counts a predator as one trophic level higher than its prey only if it significantly controls the biomass or dynamics of the prey species. Oksanen suggests that on this basis the distinction among carnivores, secondary carnivores, tertiary carnivores, and so on largely evaporates, leaving only three true trophic levels: basal species, herbivores, and carnivores—except in pelagic systems, where, due to the very small

size of the primary producers and the consequent small size of zooplankton, planktivory and piscivory emerge as truly distinct trophic roles, permitting four trophic levels. This notion that there are actually only a few trophic levels despite the existence of some very long food chains is consonant with the implications of energetics noted in the preceding paragraph.

Thus, the term “trophic level” needs to be used with caution, and if we are to speak quantitatively of trophic levels, we need to specify exactly which definition we are using and to choose a definition that sheds the most light on the particular issues of concern.

Glossary

Apomorphy A derived character or character state; if two or more taxa share apomorphies, these are referred to as synapomorphies.

Clade Group of taxa diagnosed as monophyletic by the discovery of homologies (or synapomorphies).

Cladogram Branching diagram specifying hierarchical relationships among taxa.

Cladogram support Tests that permit some evaluation of how well data fit a cladogram.

Consensus cladogram (tree) Branching diagram that summarizes the common branching patterns from two or more cladograms.

Homology Two characters passing the similarity, conjunction, and congruence tests are termed homologous; in cladistics, homology is synonymous with synapomorphy.

Homoplasy A character or character state acquired by parallel or convergent evolution that bears resemblance to a character in a different group.

Monophyly Relationship between taxa united by a synapomorphy.

Optimization Procedure for reconstructing the most parsimonious sequence of character change on a cladogram.

Parsimony General scientific principle that given alternative explanations or hypotheses for a set of observations or data, the most corroborated is that requiring the fewest ad hoc (ancillary or additional) hypotheses.

Plesiomorphy An apomorphic character or character state that specifies a more inclusive group than that under consideration.

Relationships

The basic concept of cladistics is that genealogical connections among organisms are expressed in relative terms. Consider three taxa, A, B, C, whose genealogical relationships are as given in Figure 1a. Taxa B and C are more closely related to each other than either is to taxon A because they share a common ancestor, x (which lived at time t_1), that is not shared with taxon A. Similarly, taxon A is more closely related to the group (B + C) because A, B, and C together share a unique

common ancestor, y, that lived at an earlier time (t_0). In a real example (Figure 2), the human and turkey are considered to share a unique common ancestor (w) that lived at t_3 . Similarly, the frog, turkey, and human are more closely related to each other than to either the perch or dogfish because these three taxa uniquely share a common ancestor x that lived at time t_2 . The human and turkey are called sister-groups. Likewise, in this example, the frog is the sister-group of (human + turkey). The aim of cladistic analysis is to infer the sister-group hierarchy of life-forms by analysis of characters

Figure 1 (a) The phylogenetic tree and the cladistic meaning of relationship. Taxa B and C are considered more closely related to each other than either is to taxon A because they share a unique common ancestor (x) that is not shared by taxon A. (b) Plesiomorphy and apomorphy are relative terms. On this phylogenetic tree, a' is apomorphic with respect to a but plesiomorphic with respect to a''.

Figure 2 A phylogenetic tree for five taxa of vertebrates. Three monophyletic groups are established using characters 1–6, while autapomorphic characters 7–12 diagnose the terminal taxa. The group Pisces is paraphyletic because one of its included members (the perch) is cladistically more closely related to Tetrapoda.

and to express the results as branching diagrams. These diagrams are called “cladograms” because they identify a hierarchical arrangement of taxa based on homologies termed “clades.”

Types of Characters

Two types of characters are recognized based on where they occur in the inferred phylogenetic history of a group (Figure 1b). The character that occurs in the ancestor is termed “plesiomorphic” (near to the ancestral morphology) and the derived character is “apomorphic” (away from the ancestral morphology). Apomorphic and plesiomorphic are relative terms, that is, relative to a particular systematic problem. In Figure 1b, character a’ is apomorphic with respect to character a, but plesiomorphic with respect to character a’.

Cladistic analysis proceeds by identifying shared apomorphic characters or “synapomorphies.” In Figure 2, a four-chambered heart and endothermy are synapomorphies that suggest the human and the turkey share a unique common ancestor w. The cladogram implies that these two characters

arose in ancestor w and were then inherited by both the human and the turkey. Synapomorphies may therefore be considered as evolutionary homologies. In contrast, the shared possession of internal nostrils and pentadactyl limbs by the human and turkey does not imply that they share a unique common ancestor because these attributes are also found in the frog. These shared primitive characters (or “symplesiomorphies”) are inherited from an ancestor more remote than the most recent common ancestor of the human and the turkey. They are thus irrelevant to the hypothesis of a relationship between the human and the turkey. However, with respect to the more inclusive three-taxon problem comprising the frog, turkey, and human, internal nostrils and pentadactyl limbs are relevant. At this level, they are synapomorphies suggesting that these three taxa form a group with a common ancestry at x. Apomorphies occurring in only a single terminal taxon are termed “autapomorphies.” In Figure 2, these are prismatic cartilage (dogfish), spiny fin rays (perch), pedicillate teeth (frog), feathers (turkey), and hair and mammary glands (human). However, if a terminal taxon is itself a group, then its autapomorphies are also synapomorphies of its component taxa.

Thus, as with the cladistic meaning of relationship, characters are also relative, depending on the systematic problem under consideration. Furthermore, it should be stressed that characters are observations of the features occurring in organisms and the explication of their hierarchical distribution need not imply a particular theory of evolution.

Parsimony

Relationships among three taxa (as in **Figure 1a**) can be resolved in three ways—A (B C), B (A C), and C (A B)—whereas for four taxa (as in **Figure 1b**) there are fifteen possible fully resolved cladograms. In cladistic analysis, parsimony is the universal criterion for selecting among alternative hypotheses of character distribution. Characters are fitted onto alternative topologies and the cladogram that accounts for the greatest number of characters in the simplest way is chosen as the best hypothesis of relationships.

Suppose six characters are distributed among four taxa as shown in the taxon/character matrix in **Figure 3**. Taxon A has none of the characters but the other three taxa each have a different complement. Characters 2 and 4 are autapomorphies because they are each present in only one of the taxa. They are uninformative for grouping taxa (they serve only to diagnose the terminal taxa). Characters 1, 3, 5, and 6 are potentially useful because they occur in more than one taxon. Given the three taxa that have potentially informative information, there

are three ways in which these taxa can be arranged dichotomously (**Figure 3b–d**). If the characters are now placed onto each possible cladogram, according to the groups they specify, then three different results are obtained (**Figure 3e–g**). In **Figure 3e**, all characters except one appear only once. In this solution, character 6 must be assumed to appear twice, once in taxon B and once in taxon C, which are not sister-groups. In this example, the behavior of character 6 is homoplastic, that is, it occurs more than once on the cladogram and is said to be a homoplasy. In contrast, in the other two topologies (**Figures 3f and 3g**), we must assume that two or more characters appear more than once. Hence, the cladogram in **Figure 3e** accounts for the distribution of the characters in the most economical way and is thus the preferred solution.

The distribution of characters can also be regarded as the number of steps on a cladogram, which, in **Figure 3**, is the number of instances where a character is gained. In **Figure 3e**, this is seven, while the other cladograms (**Figures 3f and 3g**) are more costly, requiring nine and eight steps, respectively. The concept of steps is actually a little more subtle than the sum of character gains because a character may appear at one point on a cladogram and then disappear at another point. For example, another explanation for the distribution of character 6 in **Figure 3e** is to assume that it is gained by the group (B + C + D) and then lost in taxon D. Each change, whether gain or loss, is considered a step. In this example,

Figure 3 Parsimony. (a) A data matrix of six characters distributed among four taxa, A–D. Plesiomorphic states are shown by open boxes and apomorphic states by black boxes. Taxon A is totally plesiomorphic. (b–d) The three possible resolutions of taxa B–D relative to A. Placing the characters on these three topologies results in (e) being selected as the optimal cladogram while (f) and (g) are suboptimal.

both accounts of character change demand two steps and therefore both hypotheses of character change are equally parsimonious. The sum of the number of steps on a cladogram is termed the length of the cladogram, irrespective of whether the changes are gains or losses. The most parsimonious solution is also known as the optimal cladogram and the other cladograms (i.e., those requiring more than the minimum number of steps to explain the character distributions) as suboptimal.

It is possible for a given set of characters to yield two or more equally most parsimonious cladograms. Then, we may prefer to accept one of the solutions based on other criteria, such as a closer agreement with the stratigraphic record or by differential weighting of one type of character change relative to another. Alternatively, we may simply accept that the conflict in the data is such that we cannot derive a unique most parsimonious solution. For certain purposes, we may choose to combine those components common to the different solutions to form a consensus cladogram.

Groups

Cladistics recognizes only monophyletic groups of organisms, which are those based on synapomorphies. Monophyletic groups are the only groups that can be circumscribed by objective boundaries. In evolutionary terms, monophyletic groups comprise the most recent common ancestor and all of its descendants. In **Figure 2**, Amniota, Tetrapoda, Osteichthyes, and Gnathostomata are all monophyletic. Two other types of “groups” are sometimes referred to but these are not groups in the same sense as monophyletic groups. Paraphyletic “groups” are based on symplesiomorphy; in evolutionary terms, their members are linked by common ancestry but one or more of the descendants of the most recent common ancestor are excluded. In **Figure 2**, Pisces (fishes) is a paraphyletic assemblage. Many taxa traditionally regarded as ancestral, such as fishes, reptiles, and green algae, are paraphyletic. Polyphyletic “groups” are based on homoplasy, that is, characters that are considered convergently derived and that cannot be inferred to have been present in the most recent common ancestor of the included taxa. In **Figure 2**, an assemblage comprising the dogfish and the turkey (perhaps based on the observation that both lay eggs surrounded by a shell, although no one would claim such a homology) would be a polyphyletic group.

Cladograms and Phylogenetic Trees

A cladogram is a diagram that summarizes a pattern of character distribution. Usually, a cladogram is drawn as a branching diagram (e.g., **Figure 1**). The nodes denote a hierarchy of synapomorphies but there is no necessary implication of ancestry and descent. Cladograms may also be written in parenthetical notation or illustrated as a Venn diagram (**Figure 4a**), which conveys the same grouping information as a branching diagram. In contrast, phylogenetic trees include a time axis and embody concepts of ancestry and descent with modification. In phylogenetic trees, the nodes denote ancestors (known or hypothetical) and the branches imply

character change. Several phylogenetic trees may be compatible with the pattern of character distribution implied by a cladogram (**Figure 4b**). Some of these trees allow the possibility that one or more taxa are ancestral to others. Only the phylogenetic tree that assumes all nodes represent hypothetical ancestors has the same topology as the cladogram. Thus, cladograms are more general than phylogenetic trees, which are precise statements about ancestry and descent.

Characters and Coding

Opinions differ over the nature and discovery of taxonomic characters. One view holds that characters are properties of organisms that provide quantifiable variation. Alternatively, characters may be viewed as theories concerning two (or more) attributes, which may look different but are nevertheless

Figure 4 Cladograms and trees. (a) A cladogram simply shows the hierarchical distribution of characters. It has no time axis and may be drawn as a branching diagram, a Venn diagram, or in parenthetical notation. Given this cladogram, several phylogenetic trees may be inferred from the same data. Some of these are shown in (b). All except that on the top left invoke the concept of one of the taxa being ancestral. The tree at the top left assumes only hypothetical ancestors and is the only one that is synonymous with the cladogram.

considered the same. This latter view is embraced within a general understanding of homology, such that characters may be understood in the same manner as homology. There is a lack of agreement over what indicates the discovery of a character. However, all definitions of homology suggest that it concerns features that are similar in different taxa sharing a recent common ancestor. Such definitions satisfy as explanations but do not aid discovery.

Homology

Within cladistics, various tests assist in establishing homology. One view of characters is that they are identical in meaning and discovery to homology, and homology may be conceived as a series of three tests that apply to methods of comparison.

The similarity “test” suggests that without evidence to allow direct comparison of one feature with another, there would be no proposition of homology and, consequently, no concept of a character. This “test” is not exact and cannot be taken to imply “identity.” For example, comparisons may consider the detailed similarity of any two stamens or the inferred similarity of mammalian stapes with gnathostome hyoid arches.

The conjunction test suggests that two features that co-occur in the same organism cannot be considered homologous. A familiar example, albeit contrived, is an angel with both wings and forearms. The two kinds of limbs in the same individual cannot be considered homologous. Many comparisons fail this test and are often associated with “homonymy” or serial homology (e.g., the individual vertebrae of a single vertebral column or the abdominal appendages of arthropods).

The congruence test is considered the most exacting and refers to the support afforded to one homology by others. In other words, homologies are considered to have passed the test if there are other homologies that specify the same taxon. Congruence is actually an analytical procedure and is usually considered in terms of parsimony. However, it also points to another property of homology, that is, homology can never be proven. As data are accumulated, previously supported homologies may be overturned and new theories of homology established in their place.

Character Recognition

It is generally agreed that characters, however conceived, are based on observations. Stated simply, a feature (e.g., stamens, shoulder girdles, wings) is observed in a particular specimen and directly translated into the character. This approach may initially seem useful and would eventually lead to enumeration of all features of the specimen. However, the final list would not consist of “characters” but would be an inventory of “features,” each being a descriptive element of the specimen and implying that such descriptions apply to all specimens of the same taxon. Each descriptive element contains a notion of theory.

Suppose the specimen examined is a rat. Initially, it would be straightforward to describe: head, body, limbs, tail, and so on. More detailed examination would reveal, for example, a vertebral column. We identify the vertebral column by

drawing on knowledge of previous studies of rat anatomy and are able to confirm its detailed similarity to other vertebral columns. In so doing, we assimilate what is already known of vertebrates: they are animals with a vertebral column. If this process were performed for all features, then it would seem that all attributes of this single rat could uncover its place in the hierarchy of life, at every inclusive level. In this sense, taxonomic characters are very much like homologies: features that (potentially) specify a particular taxon. A vertebral column does not tell us it is a rat; it tells us that it is a vertebrate. In this sense, the vertebral column is a *feature* of any particular rat but only a *character* of vertebrates. This distinction identifies the general task of systematics: to identify the level at which various attributes are homologies (characters) diagnosing taxa.

Kinds of Characters

Characters are often thought of as comprising different types. Some refer to different numbers of a feature, and others refer to differences in structure. For example, variation in stamen structure in angiosperms encompasses both different forms of anthers and filaments and differences in their numbers. This exemplifies the distinction between quantitative and qualitative characters, the former usually being counts (“meristic characters”) or measurements (“biometric characters”), the latter relating to structural differences. Quantitative characters may be problematic for cladistics insofar as it can be difficult to render measurements and counts as meaningful homology statements. This is not to say that such characters are not useful, for they can serve to identify particular specimens. However, their use may be limited because they are not always amenable to cladistic analysis.

Characters as Phylogenetic Evidence

Although structural evidence is sought for cladistic purposes, the observed features themselves are not necessarily the characters. For example, some organisms have fins, others have arms, and yet others have wings. Studies of fins, arms, and wings show that they have certain parts in common as well as certain parts that are unique. These common properties might suggest an initial proposition that fins, arms, and wings are all examples of a single character, in this case “paired appendages.” However, further details are needed to confirm this hypothesis.

Suppose the “wings” examined were from an insect such as a housefly. It might still seem reasonable to call them “paired appendages,” but in this example there is nothing in the detailed anatomy to suggest that housefly wings and mammalian arms (or even bird wings) are in any way “the same.” One conclusion is that the term “wings” is ambiguous when describing attributes of organisms but not when describing the function of these attributes (here, flight). Wings may indeed be considered as a part of an organism but flight is their assigned function (usually). A more reasonable conclusion is that “wings” is not a character at all but a functional attribute. Thus, the wing of a bird is better considered as a modified “paired appendage,” modified for flight. The problem,

however, is not simply semantic. If the comparison was made between a bird and a bat, then detailed anatomy does suggest that both are indeed “paired appendages” and that both are modified for flight. Our current understanding of vertebrates suggests that birds and bats do not form a monophyletic group. Hence, bird wings and bats wings would be considered two characters rather than one when interpreted on the cladogram (Figure 5). Their “sameness” is captured as “forelimbs,” their differences as wings of birds and wings of bats.

Consideration of the wings of birds, the forelimbs of tetrapods, and the fins of fishes together identifies a well-defined character (“paired appendages”) with various manifestations. These manifestations might suggest particular taxonomic groups. There might be a taxon with “fins,” a taxon with “arms,” and a taxon with “wings.” This, of course, was precisely the situation for many years: fishes (Pisces) have fins, tetrapods have arms, and birds (Aves) have wings (Table 1). Derived from these observations is the implication that fins, wings, and arms are in some way connected, other than by being “paired appendages”:

fins—arms—wings

Furthermore, that connection might be viewed in an evolutionary context, such that it represents the transformation of one manifestation (e.g., fins) into another (e.g., arms):

fins → arms → wings

In more general terms, features could be represented as modifications of other features, such that they are hierarchically related:

Fins
Standard fins (fins)
Modified fins (arms)
Modified arms (wings)

The features are no longer structured as a series of alternatives, as in the first example (fins—arms—wings), but now

Figure 5 Relationships of vertebrates; 1 ≡ “forelimbs”; 2 ≡ “wings of birds” 3 ≡ “wings of bats.”

Table 1

<i>Taxon</i>	<i>Character</i>
Pisces	Fins
Tetrapods	Arms
Birds	Wings

specify a nested set of relationships. The proposition is that wings are really kinds of arms, and that arms are really kinds of fins, and fins represent the entire set of animals with “paired appendages.” It is possible to interpret all of these taxa (fishes, tetrapods, and birds) as having fins. Hence “fins” is not a character of fishes but rather of gnathostomes (in this example, fishes + mammals + birds). Consequently, both the character “fins” and the taxon Pisces disappear. This view confirms the notion that characters are hypotheses drawn from observations rather than simply the observations themselves. Such hypotheses are identical to those made for general statements of homology. Superficially, the relationship between fins, arms, and wings may be considered identical to “fins → arms → wings,” as was implied by Hennig (1966) in his concept of “transformation series.” However, it is possible to view characters as more general, specifying particular relationships in terms of a definitive statement connecting to a taxon.

Character Coding

One significant outcome of theories relating to characters is how they might be represented numerically for cladistic analysis. For example, one might code each “character” (fins, wings, arms) separately (Table 2, characters 2–4). This scheme reflects the “uniqueness” of each attribute but contains no information relevant to recognizing that the three observed forms are connected as “paired appendages.” This approach is referred to as “absence/presence binary coding,” because a positive value (usually 1) is assigned to the presence of a feature and a negative value (usually 0) is assigned to the absence of the feature. Alternatively, one might represent the same series of observations in a single column to signify their connection (as “paired appendages”), then assign each unique feature a separate value (Table 2, character 1). This is “multistate coding” and considers the character to be composed of discrete states that bear some (usually unspecified) relationship to one another. Hence different values appear in the same column and are treated as dependent on the other values. This might not be seen as completely sufficient, as additional information would be needed to specify the exact nature of the connection. For instance, one might wish to specify that the “characters” are connected but that the nature of that connection is unknown. Choices of this nature relate to character optimization (see Cladistic Analysis: Optimization).

To summarize, characters have their origin, but not their identity, in observations. Characters are what lead us to suspect that taxa exist (vertebral column ≡ vertebrates ≡ taxon Vertebrata) and hence are identical to conjectures of homology derived from empirical investigation of specimens. Homology is the relation that specifies taxa and that implies

Table 2

Taxon	Characters			
	1	2	3	4
Fins	1	1	0	0
Wings	2	0	1	0
Arms	3	0	0	1

an intimate relationship between characters and taxa. Both are the results of analyses and are discovered by our investigation of features.

Cladistic Analysis

Cladogram Construction

The original method of cladogram construction was proposed by Hennig (1950, 1966) and is thus known as Hennigian argumentation. In this approach, characters are first polarized into plesiomorphic and apomorphic states. The groups thus diagnosed by synapomorphies are then organized manually into a cladogram. However, this procedure can only find the most parsimonious cladograms when the data are free or nearly free of homoplasy (i.e., the fit of data to most parsimonious cladogram is perfect or nearly so). For larger and more complex data sets, computerized algorithmic methods become a necessity.

There are two main computerized approaches to cladogram construction. Exact methods guarantee to find the most parsimonious cladograms. The simplest exact method is "exhaustive search." First, three taxa are chosen and connected to form the only possible unrooted, fully resolved cladogram for these taxa. Then, a fourth taxon is selected and added to each branch to yield the three possible fully resolved, partial, unrooted cladograms for four taxa. A fifth taxon is then selected and added to each of the five branches on these three partial cladograms to yield the fifteen possible fully resolved unrooted topologies for five taxa. This process is continued, following every possible path of taxon addition, until all taxa have been added and all possible fully resolved cladograms have been found. The lengths of these cladograms are then calculated and the shortest is chosen as the optimal solution(s). However, as the number of taxa increases, the number of cladograms to be examined rises exponentially and the time required for exhaustive search soon becomes unreasonable.

One exact method that does not require every possible cladogram to be evaluated is "branch-and-bound" analysis. In this approach, a preliminary cladogram is constructed and its length is set as the upper bound for subsequent searches. A procedure similar to an exhaustive search is then undertaken but at each step the length of the partial cladogram is recorded. Whenever this length exceeds the current upper bound, that partial cladogram is rejected (and so, consequently, are those complete topologies that would be derived from it by adding the remaining taxa). By this means, the number of topologies to be examined is reduced. Once all taxa

have been added, the length of the complete cladogram is examined and if it is equal to the upper bound, then that topology is retained as a most parsimonious cladogram. However, should this cladogram be shorter than the current upper bound, then its length is substituted as a new upper bound. This important procedure allows subsequent partial cladograms to be rejected quickly and thus speed up analysis. This process continues until all possible paths have been examined, whence the set of optimal cladograms will have been found.

For large data sets (more than 30 taxa), even branch-and-bound analysis can be too time-consuming. In this case, approximate or "heuristic" methods are used. These approaches examine only a subset of all possible topologies and thus are not guaranteed to find the most parsimonious cladogram(s). However, they are faster than exact methods for large numbers of taxa and thus certainty of finding the optimal cladogram(s) is sacrificed for decreased computational time.

Heuristic analysis comprises two stages. In the initial building phase, a cladogram is constructed using a process of "stepwise addition." The order in which taxa are added is termed the "addition sequence" and there are various ways in which taxa may be added. Once a complete cladogram has been constructed, attempts can be made to improve upon it by performing a series of rearrangements called "branch-swapping." The cladogram is cut into two or more partial cladograms, which are then recombined in order to try to find new, shorter topologies. The efficiency of current branch-swapping algorithms in finding most parsimonious cladograms is very high, but it is always possible that they can become trapped in a local optimum. Thus, one should always be aware with heuristic analyses that shorter topologies than those reported may exist.

Character Polarization and Cladogram Rooting

Manually implemented cladistic methods, such as Hennigian argumentation, require synapomorphies to be identified in advance of cladogram construction. The process through which plesiomorphic and apomorphic characters are distinguished is termed "character polarization." Numerous criteria for polarizing characters have been proposed, but only two are now considered valid.

The first criterion, called "outgroup comparison," was classified by Nelson (1973) as an "indirect" method, because it draws upon evidence from a source (the "outgroup") that is external to the taxa under investigation (the "ingroup"). In its most basic form, polarization using outgroup comparison can be defined as follows: "For a given character with two or more states within a group, the state occurring in related groups is assumed to be the plesiomorphic state" (Watrous and Wheeler, 1981: 5). This definition is adequate when all outgroup taxa share the same state, but it is insufficient if the outgroup taxa are heterogeneous. Maddison *et al.* (1984) further noted that it is inappropriate to estimate the state in the most recent common ancestor of the ingroup (the "ingroup node"). Rather, it is the state at the next most distal node, linking the ingroup to the first outgroup (the "outgroup node"), that should be estimated if the solution is to be

globally optimal, and they described an algorithmic approach to such reconstruction.

In contrast, Nelson (1973) classified the “ontogenetic criterion” as a “direct” method, because its implementation relies on evidence from the ingroup taxa alone. It is defined as follows: “Given an ontogenetic character transformation from a character observed to be more general to a character observed to be less general, the more general character is primitive (plesiomorphic) and the less general character derived (apomorphic)” (Nelson, 1978: 327). For example, the embryos of both sharks and frogs have cartilaginous skeletons. However, this condition persists into the adult shark, but in frogs the cartilage is replaced by bone during ontogeny. In this example, a bony skeleton is observed to be less general (occurring only in the frog) and is thus interpreted as apomorphic. In this context, “more general” is defined as that occurring earlier in ontogeny. As such, the more general character is not simply the more common (although this may often be the case) and the ontogenetic criterion does not equate with commonality. What is important is that the less general character is nested within the observed distribution of the more general character. This requirement is violated by ontogenetic sequences that are secondarily simplified through paedomorphosis or neoteny. Such an ontogeny cannot be interpreted as proceeding from the more general to the less general, and Nelson’s criterion will not allow us to distinguish a secondarily reduced ontogeny from the plesiomorphic sequence. Then, we rely on congruence with other characters to make the distinction.

Most recent cladistic studies do not actually include a priori polarization of characters, but undertake “simultaneous, unconstrained analysis”: “simultaneous” because both ingroup and outgroup taxa are analyzed together, and “unconstrained” because outgroup taxon relationships are unspecified before analysis. Cladograms are then rooted between the outgroup node and the remaining outgroup taxa, at which point character polarities are established.

Optimization

Optimization is the process of determining the sequence of character state changes on a cladogram in order to test hypotheses of transformation. If the data include characters coded as multistate, then these may be interpreted according to many different optimality criteria, of which the best known are Wagner and Fitch optimization.

Wagner optimization (Figure 6a–b) is used for “ordered” or “additive” multistate characters, in which transformations between successive states are considered as incremental. Thus, the changes $0 \leftrightarrow 1$ and $1 \leftrightarrow 2$ each “cost” the same number of steps (usually one), whereas the change $0 \leftrightarrow 2$ is considered to “pass through” state 1 and thus costs two steps. Costs are symmetrical, so that the changes $0 \rightarrow 1$ and $1 \rightarrow 0$ both constitute a single step (termed “free reversibility”).

Wagner optimization is implemented in two stages. First, the minimum number of steps for a character is determined. On a pass down the cladogram, from the most distal taxa toward the root, each of the internal nodes is assigned a “state set” (Figure 6a), which is defined as the intersection of the two derivative state sets. If the intersection is empty, then the

smallest closed set that includes an element of each derivative state set is assigned. For example, the intersection of the state sets of taxon F (2) and taxon G (4) is empty. Thus, the smallest closed set, (2–4), is assigned to the node linking these two taxa. In contrast, the intersection between this state set and that of taxon E is not empty. Both contain state 2, and this value is assigned to the node joining taxa E, F, and G. Unambiguous states are then assigned to internal nodes by a second pass, up the cladogram (Figure 6b), to produce a “most parsimonious reconstruction.” If the state set of a node contains more than one value, then the node is assigned the value that is closest to that of the node of which it is a derivative. Thus, the node joining taxa F and G is assigned state 2, because this is the value of the next most distal node. The most parsimonious reconstruction has six steps because the character is ordered. As a result, the change from state 2 to state 4 along the branch leading to taxon G counts as two steps.

Fitch optimization (Figure 6c–d) is used for “unordered” or “nonadditive” multistate characters in which transformations between any two states are considered equal. Thus, the changes $0 \leftrightarrow 1$, $1 \leftrightarrow 2$, and $0 \leftrightarrow 2$ all cost a single step. As with Wagner optimization, costs under Fitch optimization are freely reversible.

Fitch optimization follows similar procedures to Wagner optimization but with two differences. First, the state set assigned to an internal node is the union of the two derivative state sets (Figure 6c). Second, when determining the most parsimonious reconstruction, a node with an ambiguous state set is assigned the value of the next most distal node if that value is an element of the ambiguous state set. Otherwise, an element is selected arbitrarily. This most parsimonious reconstruction (Figure 6d) has four steps because the character is unordered. As a result, the change from state 1 to 3 along the branch leading to taxon D and the change from 2 to 4 along the branch leading to taxon G each count as a single step.

These procedures do not necessarily yield a unique most parsimonious reconstruction. For example, it is equally parsimonious to optimize the ordered character using the nodal state reconstructions shown in Figure 6d for the unordered character. State 1 is assigned to the node joining taxa C–G, and is followed by a two-step change, $1 \rightarrow 3$, on the branch leading to taxon D and a one-step change, $1 \rightarrow 2$, on the branch joining taxa E–G. The steps on the branches joining taxa B–G and leading to taxon C would be lost, thus maintaining the most parsimonious length of six steps. This type of optimization, in which changes are placed onto the cladogram as far from the root as possible, is called “delayed” or “slow” transformation. In contrast, “accelerated” or “fast” transformation places changes onto the cladogram as close to the root as possible, as in Figure 6b. When alternative most parsimonious reconstructions are possible, character optimization may lead to “spurious resolution,” in which groups appear to be resolved but have no unambiguous support in the data. Such groups are not strong hypotheses of relationship, and Nixon and Carpenter (1996) suggested that they should be eliminated wherever possible (without violating the minimum length requirement). Those cladograms that remain, which are both of minimum length and have all groups

Figure 6 Character optimization, (a) Wagner optimization (ordered multistate characters). State sets are assigned to internal nodes on the first pass from the terminal taxa toward the root. (b) States are assigned to the internal nodes on the second pass from the root to the terminal taxa. (c) Fitch optimization (unordered multistate characters). State sets are assigned to internal nodes on the first pass from the terminal taxa toward the root, (d) States are assigned to the internal nodes on the second pass from the root to the terminal taxa.

supported unambiguously by data, are termed “strictly supported cladograms” and are the preferred topologies.

Cladogram Evaluation

Character Fit

The preferred solution to a cladistic analysis is the most parsimonious cladogram because this represents the simplest explanation of the data with the number of ad hoc hypotheses of homoplasy kept to a minimum (see [Figure 3e](#)). Consequently, the most basic measure for assessing the fit of data to a cladogram is cladogram length. The most parsimonious cladogram has best fit because it is the shortest; longer cladograms have poorer fit. However, the length of the most parsimonious cladogram is partly dependent on the absolute size of the data set from which it is derived. Larger data sets will necessarily yield longer cladograms than smaller data sets. A binary character will display perfect fit when it is placed on a cladogram with a single step. Homoplasy is manifest as an increase in the number of steps. The amount of homoplasy implied by a character on a cladogram is measured by the “consistency index” (ci), which is the ratio of the minimum number of steps required by the character ($m = 1$ for a binary character) to the observed number (s). In [Figure 3e](#), character

5 occurs only once and hence its $ci = 1$ ($m/s = 1/1$), whereas character 6 shows two steps and thus its $ci = 0.5$ ($m/s = 1/2$). The amount of homoplasy implied by the whole data set can be measured using the “ensemble consistency index” (CI), which is the ratio of the minimum number of steps implied by all characters (M) to the length of a cladogram (S). For the cladogram in [Figure 3e](#), the $CI = 0.86$ ($M/S = 6/7$).

There are three perceived problems with the consistency index as a measure of homoplasy. First, although uninformative characters do not add any grouping information to a cladogram, they will inflate its CI. However, this is of significance only when different data sets are being compared. Second, CI can never attain a zero value. A data set in which all possible informative characters occur in equal numbers (an “undecisive” matrix) provides no evidence for preferring one cladogram to any other. Nevertheless, these cladograms will all have positive, nonzero CI values. Third, it has been observed empirically that CI decreases as the number of taxa increases, irrespective of change in the information content of the data. However, this is a recognized and expected property of the CI.

Although the consistency index is useful as a measure of the amount of homoplasy in a character or data set, it is indifferent to the pattern of fit on a cladogram. A binary character that occurs on two separate terminal branches will have the same ci value (0.5) as one that supports two separate groups of taxa. However, in the former case, the character

contains no grouping information, while in the latter it is a synapomorphy (albeit homoplastic) for two groups of taxa. The amount of similarity in a character that is interpreted as synapomorphy is measured by the “retention index” (ri). This is defined as $(g-s)/(g-m)$, where s and m are the same variables as for ci , and g is the maximum number of steps that a character can show on any cladogram. For character 5 in **Figure 3e**, the minimum and observed number of steps is one, and the maximum number is two. Hence its $ri = 1$ ($(g-s)/(g-m) = (2-1)/(2-1)$) and all similarity is interpreted as synapomorphy. In contrast, for character 6, the minimum number of steps is one, and the observed and maximum number is two. Hence its $ri = 0$ ($(g-s)/(g-m) = (2-2)/(2-1)$) and none of the similarity is interpreted as synapomorphy. The method can be extended to the whole data set as the “ensemble retention index” (RI), which uses the summed values of g , s , and m (G , S , and M , respectively). For the cladogram in **Figure 3e**, the $RI = 0.67$ ($(G-S)/(G-M) = (9-7)/(9-6)$).

Character Weighting

The application of differential weights to characters has a long history in systematics. Methods of weighting can be divided into a priori and a posteriori procedures, depending on whether they are applied before or after cladogram construction.

A priori approaches to character weighting generally invoke beliefs that some characters are more important than others or use a particular model of evolution or character change, under which certain types of transformation are considered more or less likely than others. For example, it is common when analyzing nucleotide sequence data to downweight transition substitutions relative to transversions. Alternatively, changes in third codon positions may be disregarded (i.e., accorded zero weight) because they are considered much more likely than changes in first or second positions as a result of the redundancy of the genetic code. Numerous other models have been proposed and they are particularly frequent in the field of molecular systematics. However, such weighting schemes are justifiable only insofar as their underlying model is justifiable.

A posteriori weighting schemes are based on “cladistic consistency” (i.e., the fit of characters to a cladogram) and characters with greater fit are accorded greater weight. One indication of a character’s fit is the amount of homoplasy it shows on a cladogram. However, homoplasy does not imply that all similarity is uninformative and the proportion of similarity interpreted as synapomorphy also needs to be taken into account. Hence, both the consistency index (homoplasy) and the retention index (synapomorphy) can be used to estimate character weights. Farris (1989) suggested using the product of these two measures, the “rescaled consistency index” (rc). By combining the ci and ri in this way, characters in which none of the similarity is synapomorphic ($ri = 0$) receive zero weight, irrespective of their level of homoplasy. All other characters, which contain some amount of grouping information ($ri > 0$), are differentially weighted according to their level of homoplasy. Using this approach, in **Figure 3e** character 5 would receive a weight of 1 ($ci = ri = 1$), but

character 6 would receive a weight of 0 ($ci = 0.5$, $ri = 0$). These weights are applied in a new analysis and the most parsimonious cladogram(s) obtained are used to estimate a new set of weights. This procedure is repeated until a stable set of both weights and most parsimonious cladograms is achieved; hence the name “successive approximations character weighting.”

The level of homoplasy of a character may also be viewed as the number of extra steps required to fit it to a cladogram. If all extra steps in all characters are considered equal, then a linear fitting function is being applied to their relative cladistic consistency. For example, in **Figure 3e**, the single step of character 5 is considered equal to each and either of the two steps of character 6. However, intuitively, we might consider that characters showing fewer extra steps are “better” than those showing more. The former can be assigned higher weights than the latter using a concave fitting function of relative cladistic consistency. This approach was implemented by Goloboff (1993) as “implied weighting,” in which the weight (W) accorded to a character is calculated as $W = K/(K + ESi)$. ESi is the number of extra steps shown by the character and K is the “constant of concavity.” The value of K can be varied to weight more or less strongly against those characters with the most extra steps. As K decreases, these characters will receive progressively lower weights. For example, in **Figure 3e**, character 6 will receive a weight of 0.85 when $K = 6$, but a weight of only 0.5 when $K = 1$ (the “perfect” character 5, which has no extra steps, receives the maximum weight of 1). The optimal cladogram is that for which the summed weights for all characters has the largest value.

Consensus Cladograms (Trees)

A cladistic analysis will often produce more than one most parsimonious cladogram as a result of contradictory signal in the data (homoplasy). The agreement between such “fundamental cladograms” (so-called because they are generated directly from the analysis of data) can be conveniently summarized by means of a consensus cladogram (usually referred to as a consensus tree). Several consensus methods have been proposed, of which the most widely used are “strict,” “combinable components” (or “semistrict”), “Adams,” and “majority-rule.”

The strict consensus tree is the most conservative, because it includes only those groups (often referred to as “components”) that are common to all the fundamental cladograms. For example, in the two cladograms shown in **Figures 7a** and **b**, only groups ABC and DEF occur in both, and thus these are the only groups that appear in the strict consensus tree (**Figure 7d**). Groups EF, AB, and BC are excluded because the first is lacking from **Figure 7b** (where it is unresolved) and the other two are contradictory.

However, it is possible for a group to be lacking from one or more fundamental cladograms and yet be uncontradicted. For example, group EF in **Figure 7a** does not conflict with the cladogram in **Figure 7b** because it is one of the three resolutions possible for the group DEF. Combinable components consensus allows such non-replicated, but non-conflicting, groups to be included in the consensus tree, in addition to those groups in common (**Figure 7e**). When all fundamental

Figure 7 Consensus analysis. (a–c) Three cladograms for six taxa, A–F. (d) Strict consensus tree of cladograms 7a and 7b. (e) Combinable components consensus tree of cladograms 7a and 7b. (f) Strict consensus tree of cladograms 7a and 7c. (g) Adams consensus tree of cladograms 7a and 7c. (h) Majority-rule consensus tree of cladograms 7a, 7b, and 7c.

cladograms are fully resolved, with no spurious resolution due to ambiguous optimization, then the strict and combinable components consensus trees will be the same.

A problem with both strict and combinable components consensus is that a single taxon appearing in highly disparate positions on two cladograms is sufficient to collapse all intervening resolution. For example, taxon D in **Figures 7a** and **c** appears as the sister-group to two different terminal taxon-pairs. Consequently, the strict consensus tree (**Figure 7f**) is relatively unresolved. However, examination of **Figures 7a** and **c** shows that taxon D is acting as a “rogue” taxon; that is, apart from its differing positions, the resolution of the remaining taxa is identical in the two cladograms. Such rogue taxa can be identified using Adams consensus analysis. On an Adams consensus tree, taxa in conflicting positions on the fundamental cladograms are placed at the most inclusive node they have in common; in other words, the consensus contains all intersecting sets of taxa common to the fundamental cladograms. However, as a result, it is possible for an Adams consensus tree to contain groups that are not found on any of the fundamental cladograms and thus they need to be interpreted with care. Sometimes taxa such as D

would simply be deleted to give the “largest common pruned tree” as a consensus.

When the number of fundamental cladograms is large, strict consensus trees are often very poorly resolved and can be viewed as too restrictive. One method of increasing resolution of the consensus is to retain those groups that occur in a pre-specified number of the fundamental cladograms. Typically, such majority-rule consensus trees will comprise those groups that occur in more than 50% of cladograms. The majority-rule consensus tree of the cladograms in **Figure 7a–c**, shown in **Figure 7h**, is fully resolved, despite the marked topological differences in its fundamental cladograms.

Regardless of their number, the most parsimonious cladograms found by cladistic analysis remain our best estimate of the relationships among the taxa under study. Because resolution is lost, most consensus trees are less parsimonious than their fundamental cladograms. However, if the topological differences among the fundamental cladograms are due solely to ambiguous optimization, the strict consensus tree will also be of minimum length. Then, the strict consensus tree is also the strictly supported cladogram (Nixon and

Carpenter, 1996) and is the preferred most parsimonious topology because it is the only cladogram that is both of minimum length and has all groups supported unambiguously by data.

Cladogram and Group Support

A number of statistics attempt to assign levels of support or confidence to the results of cladistic analyses. They can be divided into two categories: methods that address support for an entire cladogram and aim to determine whether there is any “significant” structure in the data, and methods that examine the support afforded to individual groups on a cladogram and attempt to distinguish those groups that are well supported from those that are not.

Methods aimed at assessing support for an entire cladogram all use the same general principle. The length of the most parsimonious cladogram obtained from the observed data set is compared with those derived from a large number of “phylogenetically uninformative” data sets, with the expectation that the former will be substantially shorter than any of the latter. Several definitions of “phylogenetically uninformative” data have been proposed, including “statistically random” (scores in a data matrix are allocated at random), “undecisive” (all possible informative characters occur in equal numbers), and “randomly co-varying.” The last of these forms the basis of the “permutation tail probability” (PTP) test. Covariation here is the degree to which characters are explicable by the same cladogram (i.e., congruence). A most parsimonious cladogram that contains a large amount of homoplasy may be derived from data exhibiting such poor covariation that randomly co-varying characters could produce a cladogram of equal length or shorter. The PTP test uses pseudoreplicate data sets in which character codes are randomly reassigned to taxa, with the restriction that the proportion of each code is maintained, and with each character treated independently. For example, for three taxa (A, B, and C) originally coded 0 and two (D and E) coded 1, permutation may reassign 0 to A, C, and D and 1 to B and E. This procedure is repeated to create a large number of such pseudoreplicates, for which the most parsimonious cladograms are then found. The PTP is defined as the proportion of all data sets (original plus permuted) that yield most parsimonious cladograms at least as short as the original data set and may be interpreted as the probability that a cladogram of this length could have arisen by chance.

The simplest measure of support for a particular group on a cladogram is branch length. However, homoplasy makes the assessment of branch support difficult and groups may appear to be better supported than they actually are. “Bremer support” is a more precise measure of clade support and is defined as the number of extra steps required to lose a clade from the strict consensus tree of near-minimum-length cladograms. When there is no homoplasy in the data, the Bremer support of a group is the same as its branch length. Otherwise, support is reduced to the extent that there are alternative equally parsimonious groupings. To calculate Bremer support, first those cladograms that are one step longer than minimum are found and the strict consensus tree formed from them and the most

parsimonious cladogram. The process is repeated, adding a step at a time, until the group in question is lost from the consensus. The number of extra steps required to achieve this is the Bremer support for the group. If more than one most parsimonious cladogram is found initially, then the procedure begins with the consensus tree of these cladograms. Any group that may be a potential resolution of the consensus will have a Bremer support equal to 0.

The bootstrap seeks to estimate group support using pseudoreplicate data sets, which are formed by randomly sampling characters with replacement. The effect is to weight some characters and delete others, with the constraint that the total weight equals the original number of characters. A large number of such pseudoreplicates are generated and their most parsimonious cladograms are found. Conflict among these cladograms is assessed using a majority-rule consensus tree and the support for a group is estimated as the proportion of most parsimonious cladograms on which it is recovered.

However, both the PTP test and bootstrap are questionable in a cladistic context. The PTP test’s null hypothesis of randomly co-varying characters is contrary to the basis of cladistics. Characters as nested homology statements are intrinsically hierarchical and thus it is inappropriate to measure their performance against randomized characters from which this hierarchy has been removed. The bootstrap assumes that a data set represents a random sample of all possible characters. However, taxonomic characters are generally carefully selected with the aim of resolving the relationships of the taxa under study. Furthermore, it only requires a single synapomorphy to diagnose a clade. However, the random nature of the bootstrap process means that such a character may be represented in only a few pseudoreplicates and thus the group will not appear in the majority-rule consensus tree despite being uncontradicted. Thus, bootstrap values are a one-sided test; recovered groups have some measure of support in the data, but groups that are not recovered cannot be rejected.

Simultaneous and Partitioned Analysis

It is generally recognized that data from many sources may be used in a cladistic analysis (e.g., morphological, physiological, behavioral, ecological, or molecular sequences) and that analyses of these data can yield different hypotheses of relationships. Simultaneous analysis (sometimes called a total evidence approach) combines all data, from whatever source, into a single taxon $\times$ character matrix for analysis. The resulting hypothesis of relationships is thus determined by character congruence (Figure 8a). Alternatively, different classes of data may be analyzed separately and the resulting cladograms added together using a consensus method to extract the common phylogenetic signal. This is called the partitioned evidence approach (Figure 8b) and the result is determined by taxic congruence. The reasoning underlying this approach is that different classes of data may reflect different evolutionary processes and so should be analyzed separately. A third alternative, known as conditional data combination, attempts to distinguish those conditions under which it would be best to keep data sets separate and conduct partitioned evidence analysis from those conditions under

Figure 8 Simultaneous and partitioned analysis. In simultaneous analysis, all data are combined into a single matrix before analysis. In partitioned analysis, each data set is analyzed separately and the resulting cladograms are then “added” together using a consensus method.

which it is more appropriate to conduct a simultaneous analysis. This approach estimates the degree of heterogeneity of phylogenetic signal among data sets, and if the heterogeneity is greater than might be explained by sampling error, then the data sets are analyzed separately.

Glossary

Adaptation Any genetically controlled characteristic that increases an organism's fitness, usually by ensuring the organism to survive and reproduce in the environment it inhabits.

Adaptive radiation The evolution of one or a few forms into many different species that occupy different habitats within new geographical areas or habitats.

Anagenesis A pattern of evolutionary change involving the transformation of an entire population, sometimes to a state different enough from the ancestral population to justify renaming it as a separate species; also called phyletic transformation of an un-branched lineage of organisms which changes to such an extent as to be justifiably called new species or taxa. This is considered "biological improvement" (sensu Huxley, 1958), covering all types of change from detailed adaptation to generalized organizational advance.

Clade The branch between the nodes on a cladogram or phylogenetic tree; the unit of cladogenesis.

Cladogenesis Branching evolution; the origin of diverging new forms from an ancestral lineage; the form of divergence and phyletic splitting, including speciation; adaptive radiation of species to major divergence of families and phyla. Evidence for cladogenesis is from those fossil groups that increase in the number of recognizable taxa over time.

Genotype The genetic constitution of individuals, species and taxa.

Grade The product and "unit" of anagenesis; paraphyletic group.

Linnean system/hierarchy The hierarchical arrangement of inclusive categorical ranks in which, apart from the lowest rank, subordinates members of all lower ranks; it contrasts with exclusive classifications (e.g., *scala naturae*).

Monophyly (monophyletic group) A natural group that includes a most recent common ancestor and all of its descendants.

Natural classification Systems of classification portraying as accurately as possible the entire pattern of life and its relationships.

Ontogeny The developmental history of an organism from egg to adult. Includes embryogenesis that describes the generative phase and the allometric phase of growth and maturity.

Paraphyly A group that includes a most recent common ancestor and only some, not all, of its descendants.

Phenotype The characteristics of an individual and all its parts as an interaction between the genotype and the environment.

Phyletic Line(s) of descent between ancestors and descendants.

Phylogeny The inferred lines of descent showing genealogical relationships of organisms; often used to describe nested series of monophyletic taxa both in cladograms and phylogenetic trees.

Polyphyly (polyphyletic group) A group that does not include the most recent common ancestor of all of its members.

Punctuated equilibrium The morphological stasis of fossil species over long periods of time punctuated by seemingly instantaneous speciation and morphological change.

Scala naturae (Great Chain of Being) One of the most pervasive ideas in western thought derived from two concepts Plato's principle of plenitude and the linear series of Aristotle and Plotinus (Panchen, 1992); in plain English, the belief in a linear progression from the simplest forms of life to the most perfect.

Stasis (stasigenesis) The persistence of organisms through long geological periods of time that greatly resemble their fossil forebears. The "process" is used to recognize delimitable anagenetic units, or "grades."

Synapomorphy Shared derived characters; homologies of monophyletic groups.

Tree of porphyry A tree classification constructed as a dichotomous key that at any rank divides on the basis of differential characters to give two taxa at the rank below. The net result is a comblike branching diagram intended to classify individuals within a general scheme.

Diversification—Patterns and Process

The terms anagenesis (divergent evolution), cladogenesis (branching evolution or diversification), stasis (stasigenesis; constancy), grades, and clades are all associated with mechanisms and patterns of phyletic evolution. Anagenesis is evolutionary change in lineages through time, cladogenesis is

diversification of clades by branching of lineages through time (Rensch, 1959), and stasigenesis (stasis) refers to persistence of lineages through time (Huxley, 1958). The distinctions came about through the belief that in evolution there were three main processes at work that led to "biological improvement," to "diversification," and to "persistence." Extinction, although seen by some to be of importance in evolution,

is perceived as a failure to persist and is now treated as an important part of diversity assessments of life on earth. The concepts of phyletic evolution came to prominence in the neo-Darwinian synthesis of genetics and evolution, but their meanings changed when viewed through the lenses of different systematic perspectives. Grades, for example, once seen as extremely important with respect to the pattern of evolution in the scala naturae, are now seen as artifacts, described as paraphyletic and polyphyletic groups in the literature of cladistics where the emphasis lies in the analysis of clades and the recognition of sister groups. Furthermore, the processes of anagenesis and cladogenesis refer either to microevolutionary processes (speciation) or to patterns and rates of evolution through geological time calculated as rates of morphological, taxic, and molecular change.

The centerpiece of evolutionary theory is that the environment varies with time and from place to place. Heritable variations that suit a particular environment are selected *in situ*, and so with time populations diverge and differentiate as each becomes adapted to its own conditions (Patterson, 1999). Darwin (1859) considered that such adaptive change led to diversity of form, with features thought to result from the process of diversification. Cetaceans and sea grasses, for example, are thought to be marine-adapted mammals and flowering plants, respectively, with land-borne ancestors. With the impact of tremendous changes in systematic thinking and population biology, Darwin's theory of organic evolution is now considered by most people to be the only worthy explanation of the diversity and form of life on earth. Darwin's theory has two quite different and distinct aspects. Evolution by common descent is used to describe the patterns of changes in diversity through time, and evolution by natural selection describes the processes leading to diversity as a measure of change over time.

The language of micro- and macroevolution emerged at a time when fossils were considered as of cardinal importance for understanding the patterns and processes of evolution, when evolutionary theory, which was making great strides by amalgamating with genetics and evolutionary systematics, had yet still to mature. Evolution is the key. However, the greatest strides over the past 30 years have been made in systematics, where fossils have been analyzed together with recent taxa. The relationships have changed, and systematics is the key. Progress in evolutionary theory has largely been in mechanisms. The concepts of cladogenesis and anagenesis have consequently changed. For example, as interpreted in the light of phylogenetic systematics (or cladistics) grades pertain to polyphyly and paraphyly, and clades to monophyly. The origin of species or higher taxa by anagenesis, cladogenesis, or phylogenesis, and persistence through stasis, is associated more with process biology in microevolution (see speciation processes) and particularly the assessment of patterns and rate of macroevolution.

The Synthetic Theory

The synthetic theory of natural selection (often described as neo-Darwinism) incorporates the original theory of natural selection of Darwin and Wallace (Darwinism) but also incorporates models of population genetics and the underlying

bases of morphological and genetic heterogeneity within organisms. Classic genetic studies on model organisms such as *Drosophila*, *Cepaea*, and mimetic butterflies (see Panchen, 1992) have largely been concerned with genetic variation on different alleles in heterogeneous populations and the consideration of adaptive significance, which led to the rather stifling view that all change is adaptive. This has led to the idea that natural selection is essential for adaptive, anagenetic change and is a necessary precondition for cladogenesis (speciation). The processes of anagenesis, cladogenesis, and stasis are used to describe changes (or the lack thereof) in phenotypes and genotypes through changes in the environment both in space and time and by mutations and heritable variations within phylogenetic lineages. Patterns of diversity are described in phylogenetic schemes or genealogical trees through systematic analysis.

Speciation

As Huxley (1958) noted, Darwin (1859) recognized three processes at work "leading respectively to biological improvement, to diversification, and to persistence." Improvement covers adaptation to specialized lifestyles, through phyletic transformation of lineages, resulting in the derivation of descendent species directly from ancestors. These are recognized as "transformational" or "evolutionary" species. New species arise as recognizable transformations within a lineage, by-products of the genetic properties of the lineage, and are thus recognized as arbitrarily divided segments of that lineage. Diversification covers all patterns and processes from micro-morphological changes and subspeciation (microevolution), adaptive radiation (cladogenesis with adaptation), and macroevolution, the division into major phyla and higher taxa. Thus, the processes of divergence include lineage splitting, speciation, and adaptive radiation where genetic isolating mechanisms result in two or more descendants derived from a common ancestor. Persistence refers mostly to the idea that organisms of great geological age survive unchanged as living fossils into contemporary biotas. Little or no detectable change takes place through time such that the modern organisms resemble fossils from early geological periods. Examples include animals, such as *Latimeria* (Coelacanth), *Nautilus*, and *Sphenodon*, and plants, such as *Ginkgo* (Maidenhair tree), *Wollemia* (Wollemi Pine or "dinosaur tree"), and the *Metasequoia* (dawn redwood).

Anagenesis, Cladogenesis, and Stasis

New species can either become modified through gradual change in an entire lineage in response to a changing environment or can emerge through diversification into two or more species through formation of internal and external isolating mechanisms. Anagenesis is gradual change in an entire lineage (Figure 1). Division into two or more species is termed cladogenesis (Figure 2). There are many modes of population differentiation and considerable debate as to their roles in speciation. Likewise the mechanisms for anagenesis and cladogenesis (speciation) are many and varied. Nevertheless, they

Figure 1 Anagenesis. The transformation of a species or taxon on an unbranched lineage of organisms. Divergence has occurred to such an extent that it is justifiably called a new species or taxon.

Figure 2 Cladogenesis. The transformation of a species or taxon into two (or more) species (or taxa) by branching along a lineage.

Figure 3 Phyletic gradualism. A fairly constant rate of change through time.

all include some form of population differentiation, either by gradual change of genetic differences and natural selection (phyletic gradualism), or by abrupt punctational changes, involving chromosome inversions or translocations and rapid isolation between populations, or by historical accidents, such as allopatric speciation by vicariance and isolation.

There is considerable controversy among the theories of diversification and how evolution proceeds. The Darwinian hypothesis is phyletic gradualism, whereby the same micro-evolutionary processes that lead to population differentiation cause ever-increasing divergence between populations (**Figure 3**). Eventually, sufficient divergence has occurred for differentiation at species level to be recognized. Differentiation continues at a steady rate and new species originate by

Figure 4 Punctuated equilibrium. Morphological stasis of fossil taxa over long periods apparently punctuated with occasional instantaneous change.

slow, gradual changes of ancestral species. The neo-Darwinian perspective is that evolutionary transformation takes place within species, or lineages, and the branching process of cladogenesis accounts for diversification but relatively small amounts of evolutionary change.

An alternative theory of evolutionary rates and speciation, punctuated equilibrium, was proposed by **Eldredge and Gould (1972; Figure 4)**. Evidence from paleontology on well-preserved fossils indicate long periods of stasis, where “species” remain relatively little changed over long periods of time. At other times there appears to have been rapid evolution and great morphological differentiation. **Eldredge and Gould (1972)** thus concluded that rates of evolution were not constant over time. They hypothesized that little evolutionary change occurs within species and that genetic changes within populations do not account for different species. Instead, the events of speciation account for evolutionary change, and short periods of “punctuation” were interspersed with little or no evolutionary divergence.

Phyletic gradualism and punctuated equilibrium represent the opposite extremes of a continuum. Recent research, especially on rates of molecular change, would suggest that evolutionary rates are clocklike, or at least “clocky,” caused by periods of slow rates of phyletic change and rapid periods of cladogenesis. This is reflected in research of the 1980s and 1990s, which has concentrated on uncovering the patterns of divergence through systematic analysis (particularly cladistics). Sustained application of cladistic methods has determined nature’s hierarchy and techniques such as maximum likelihood have been used to assess rates of change amongst phylogenetic trees.

Clades, Grades, Gossils, and Ancestors

Systematic classifications are represented in branching diagrams, variously known as trees, phenograms, dendrograms, and cladograms depending on which systematic philosophy is being used. For most practicing biologists of the 20th century, modern systematics dates back to Linnaeus. He recognized that nature’s hierarchy could be arranged into a series of

named categories. His system of categories, although still in use today, is somewhat arbitrary, based on the predefined levels of *Regnum* (Kingdom), *Classis*, *Ordo*, *Genus*, and *Species*, to which Phylum and family were later added (Panchen, 1992). All the members of the same level were given the same rank. As distinct from exclusive systems, such as military ranks, biological ranks are all inclusive and genuinely hierarchical, whether viewed agglomeratively from the bottom or divisively from the top, such that eventually all taxa belong to one group, life itself. The hierarchy is divergent, so that a taxon of, say, a specific rank, belongs to a taxon of higher rank and the taxon of this rank belongs to a taxon of even higher rank, and so on. The hierarchy is not necessarily symmetrical, because taxa of high rank can have everything from one isolated member to a great number of members. Elements of Linnean system are still in use today, especially nomenclature, but its avowedly artificial category hierarchy, expressed as a pre-ordained ranking system, has become replaced by a whole succession of “natural” classification systems portraying as accurately as possible the entire pattern of life and its relationships.

Natural Classification

Almost a century of debate has questioned the meaning of “natural” classification systems but by the time that the *Origin*

was published (Darwin, 1859), the form of representation had become a branching diagram of hierarchical clusters. To his credit, Darwin made the tree metaphor explicit in what was the only diagram published in the *Origin* (Figure 5). This was not a diagram produced by clear-cut rules but a tree rooted in the past—a genealogical tree to denote phylogeny in a vertical direction and classification of relative distances of present-day organisms in the branching hierarchy. One of the most important issues that came from Darwin’s evolution by common descent was that phylogeny is the theory that underpins natural classification today.

Fairly soon after the *Origin* appeared, “forests” of genealogical trees began to appear in the European literature. Perhaps the most memorable rendition of all schemes ever published is that of Haeckel (1874) who used literally the European oak (*Quercus robur*) to synthesize his interpretation of phylogeny and classification and the origin of man into a natural classification using Darwin’s tree metaphor (Figure 6). Apart from its shape, the named parts of the tree embody two quite separate concepts. The shape is simple enough in that it depicts a multifurcating inclusive genealogy with the names of the branches indicating monophyletic groups (groups derived from a common ancestor). However, the names on the vertical axis, horizontal lines or “grades” of evolutionary achievement, embody a watered down version of the *scala naturae*, a belief in the progression from the lowliest simplest forms of life

Figure 5 Darwin's (1859) branching diagram from the *Origin*. Note that A–L represent the species of a genus. The small letters show degrees of divergence through time. The horizontal lines represent 1000 or more generations. The diverging lineages are shown with extinct populations at most generations in every lineage. Reproduced from Darwin C (1859) *The Origin of Species by Means of Natural Selection*. London: Murray.

Figure 6 Haeckel's (1874) "literal tree" (European oak) depicting human ancestry as interpreted by Darwin's theory of evolution by common descent. The bifurcating branches indicate groups determined on embryology and the vertical axis (conflated with time) represent grades. Reproduced from Haeckel E (1874) *Anthropogenie: Keimes- und Stammes-Geschichte des Menschen*, 1st ed. Leipzig: W. Engelmann.

Figure 7 Abel's concept of Stufenreihe (clades A–D) and Ahnen-reihe (grades a–d). See text for explanation. Reproduced from Figure 3.6 in Panchen AL (1992) *Classification and Evolution, and the Nature of Biology*, 55 pp. Cambridge: Cambridge University Press.

Figure 8 "Bessey's cactus". Diagram to show the relationships of orders. The size of each order is represented by the shape and dimensions of each component of the diagram. For an explanation of a, b, and c, see text. Reproduced from Figure 1 in Bessey CE (1915) *The phylogenetic taxonomy of flowering plants. Annals Missouri Botanical Garden* 2: 109–164.

(Monera) to the most "perfect" (human) through the series protozoa—metazoa—evertabrata—vertebrata—mammalia. The distinction was based on Haeckel's twin concepts of the evolution of the foetus, ontogeny, and recapitulation in the evolution of the stem (phylogenesis). Arising out of former was the phylogenetic interpretation of the *Tree of Porphyry* as a step series (Stufenreihe) and distinguished from the ancestor series (Ahnenreihe) in palaeobiology (see Panchen, 1992).

By the turn of the 20th century, branching diagrams were largely depicted as phylogenetic trees to represent "Ahnenreihe" as "grades" in ancestor-descendant series and "Stufenreihe" to represent evolution by cladogenesis into a succession of adaptive zones (Panchen, 1992; Figure 7). There have been endless variations of this theme in comparative biology and different emphases placed on grades and clades. For example, Bessey's cactus (1915), deliberately emphasized grades and even interpreted extant supraspecific taxa, Ranales (Figure 8a), as giving rise to other supraspecific taxa, Rosales (Figure 8b), which in turn gave rise to Myrtales (Figure 8c). At the other extreme, Janchen's (1932) interpretation of Wettstein's classification clearly emphasizes clades with grades added almost as an afterthought to indicate the distribution of floral evolution through gymnospermae/angiospermae, apetalae/sympetalae, and monocotyledony/dicotyledony (Figure 9).

Grades and Clades in Evolutionary Systematics

These days we know that Bessey's approach is untenable—one supra-specific taxon cannot give rise to another. The Ranales cannot be the ancestor of the Rosales, and even if we did consider them to have an ancestor-descendant relationship then the Ranales and Rosales would have to be classified in the same group rather than as depicted in Figure 8. Nevertheless, grades and clades are still established practice and appear in textbooks even today. The 20th century has seen an enormous output of different phylogenetic schemes and the persistence of grades has pervaded the methods of "evolutionary systematics." The idea that grades are important in systematics so as to express patterns of anagenesis is the hardest notion to expunge. Grades are characteristic of classifications involving "satellite" groups considered sufficiently divergent to separate them at a high rank from their nearest relatives. The more "primitive" taxa are similarly rendered as a grade, a paraphyletic group in the language of phylogenetic systematics or cladistics.

To illustrate, perhaps the two most famous examples include human (*Homo sapiens*) considered superior to its primate relatives, and birds (Aves) considered greatly diverged from relatives in the class Reptilia (Figure 10; see Mayr, 1974; Panchen 1992). The net effect of such schemes is that the phylogenetic reconstruction, based on character analysis, differs greatly from the written classification. Figure 10 illustrates this result in both examples. Thus for the diapsid reptiles the phylogenetic diagram shows ancestor A ancestral to two groups B (Diapsid reptiles) and C + D (crocodiles + birds). The classification differs in that group D (Aves) shows such considerable divergence along the horizontal character axis (the anagenetic component), that to express the information in a classification puts B + C together (diapsid reptiles + crocodiles) and D is kept separate (Aves). A similar story can be portrayed for orangutan + gorillas/chimps and *Homo sapiens*. The phylogenetic diagram shows C + D (gorillas/chimps and humans) as sister group to B (orangutan) but the classification puts B and C together and humans in a group D of their own. Mayr (1974) claimed that the anagenetic component should carry more weight because of many genes shared in common among birds and not found in the nearest relatives and because of the unique

Figure 9 Grades and clades, Janchen's (1932) phylogeny. The phylogeny of the seed plants is shown as a branching diagram. Grades are depicted by irregular, thick black lines crossing the branches of the phylogeny. Reproduced from Janchen E (1932) Entwurf eines Stammbaumes der Blütenpflanzen nach Richard Wettstein. *Öster. Bot. Zeit* 81(3): 161–166.

Figure 10 Grades and satellite groups. A = ancestor; B = diapsid reptiles, or orangutan; C = crocodiles, or gorillas/chimps; D = birds, or humans. See text for explanation.

behavioral characters in man. Thus, groups represented by D are placed in higher grades and groups represented by B + C in lower grades.

Paraphyly and Monophyly in Cladistics

Cladistics demonstrates that grades are impossible to characterize as they do not express relationships between organisms. There is no way of knowing when one grade starts and another

Figure 11 Definition of relationship in (a) a cladogram and (b) a Venn diagram.

stops. How many characters along a branch are required before it is possible to draw a line and say that one side represents a lower grade and the other side a higher grade? Related to this question is how many taxa belong to a grade group?

Hennig (1996) described a method to implement evolution by common descent by reconstructing phylogenies based on assessments of speciation (cladogenesis) and transformation of characters (now known as cladistics; see *Methods of Systematics, and Cladistics*). His most important contribution was to offer a precise definition of relationship and a technique for those relations to be discovered. A minimum of three taxa is necessary to express a relationship. For example, in **Figure 11a** taxa B and C are more closely related to each other, than either is to A, because they share a common ancestor not shared by A. Cladistic analysis finds monophyletic groups on the basis of uniquely derived, shared characters (synapomorphies).

Figure 12 Cladograms and trees: (a) cladogram, (b–e) a selection of phylogenetic trees consistent with the cladogram in (a).

Hennig showed that monophyletic groups are “natural groups,” that branching nodes expressed relations, and that synapomorphies are the only measurable quantities for determining pattern. Hence neither horizontal nor vertical branches (anagenesis) are meaningful for expressing relationships on cladograms or for the determination of groups. Vertical branches say nothing about time and the relative nesting of nodes on the cladogram provide only relative rather than absolute estimates of ordinal time. Relationships could just as easily be represented by nested sets or Venn diagrams (Figure 11b).

Cladograms are synapomorphy schemes, induced from the most parsimonious distribution of characters to show sister-group relationships. In Figure 12a, taxa B and C represent one sister group nested in larger sister group, A and B + C. Cladograms are different from phylogenetic trees because they rely entirely on empirical data, taxa, and characters. They express only the general branching pattern of life because that is all that is available from analysis of taxa and form. The strongest support for this idea is that many phylogenetic trees can be hypothesized for the same cladogram irrespective of branch length (Figures 12b–e). Consequently, anagenesis, ancestors, and ancestor-descendant relationships are not directly available from character analysis but require models of one kind or another to arrive at answers to questions of rates of divergence. Cladograms are different from phylograms or phylogenetic trees because they are isomorphic with the classification. Cladograms are consistent with name hierarchy and they can be recovered from written classifications. On the basis of this property, Hennig (1966) justifiably claimed that phylogenetic systematics provided the only truly general reference system consistent with the theory of evolution by common descent.

The task of systematics for Hennig was to understand natural relationships (monophyly, monophyletic groups) and rid the general reference system of polyphyly and paraphyly. Although there has been considerable proliferation in the methods and sources of information in systematics, the main effect has been to put intense effort into cladogenesis by the discovery of clades or monophyletic groups. For the past 25 years or so systematics has concentrated on determining the pattern of life from its earliest beginnings to the highest nodes on the tree, especially as a result of massive strides in molecular biology. Programs in pattern analysis range from the minutiae of phylogeography within species and populations to the

discovery of monophyletic clades throughout the entire history of life. On the process side have been intense efforts to discern the rates of macroevolution by calibrating what is known about fossil history and morphological evolution with what is known about base substitution rates in ubiquitous molecules.

Patterns of Life

The emphasis over the past 30 years has switched from worrying so much about whether one species or taxon gave rise to another species or taxon to emphasizing phylogenetic trees and cladistic patterns. The emphasis has switched entirely from ancestor-descendant stories to expressions of sister-group relationships. The emphasis on the overall morphology and anatomy of the phenotype has comparably given way to the use of molecular characters. Furthermore, the discovery that sequences of amino acids of protein chains and nucleic acids contain detailed sources of information has given impetus to the discovery of family trees across the entire hierarchy of life. By comparing homologous amino acid or gene sequences it has been possible to compile family trees using computerized cladistic analyses with thousands of taxa in one calculation. Through a massive empirical enterprise, involving literally thousands of published investigations, the stage has been reached when comparisons between bacteria, flowering plants, and mammals in the same analysis are a reality. The potential for observing the patterns on both a grand scale and at species level is dominating comparative biology in all disciplines. The output of data and cladograms is so vast and the information coming from a variety of museums and laboratories around the world that dedicated web sites are being built to make sense of it all (see, for example, The Tree of Life web page at <http://phylogeny.arizona.edu/tree/phylogeny.html>).

The overriding message from all of this empiricism is that large-scale differences between humans, mice, elephants, and oak trees have the same sort of causes as closely related species (Patterson, 1999). It appears that at all scales of investigation the differences between organisms related by common ancestry owe their differences to divergence, the accumulation of mutations over great periods of time. The evidence for this homology comes from the fact that organisms share homologous features at many levels, molecular, structural, and

physiological. At face value it would seem that gradual phyletic evolution would explain changes in both micro- and macro-evolutionary events. Several evolutionists have different opinions about this. They can accept point mutations, gene duplications, and chromosome mutations to explain the smaller divergences in birds and butterflies but require other mechanisms to suggest the massive differences between fishes and land organisms or the original appearance of crustacea and green plants. The main reason for requiring macromutations for macroevolution is that many features of major groups cannot be imagined to have come into being by small adaptive changes. The point often made is the existence of complex organs. Familiar questions are of what use is half an eye or half a lung? The answers are not readily apparent because the evidence is unclear. The intermediate steps cannot be imagined. By improving the accuracy of reconstruction of cladograms for the whole of life the potential exists for assessing whether the story is one of gradual phyletic evolution or not.

Rates of Evolution

Rates of evolution have always been of interest to systematists and evolutionists alike, and one of the popular myths is that the fossil record is the only direct evidence to track the course of evolution. During the history of paleontology many arguments have been constructed to link the fossil record to evolution because we know that fossils are the remains of once living organisms and they predate the rock sediments in which they lie (Panchen, 1992). Furthermore, the idea that the stratigraphic record encapsulates the historical record, and that most fossils are extinct but related to modern groups that extend a little way back in time, is the underlying justification for schemes to correlate the pattern of fossil record with evolution through time. It has long been considered possible to calculate different rates for a number of reasons. "Living fossils" that have survived from the geological past to the present-day show that most organisms in the fossil record were once living but are now extinct. Similarly, "Lazarus" taxa, found in an early geological period, which then disappear for millions of years to reappear in more recent periods, were considered to be a good line of evidence to support phylogenetic reconstructions with absolute, rather than relative time, intervals. The fact that many modern groups are modified older groups and can be traced back in time has reinforced evidence for the transmutation of fossil organisms into modern forms and hence the belief that rates of evolution can be calculated.

Morphological Evolution

Perhaps the most cited examples of evolution between fossils and modern taxa are the so-called missing links. Fossils, such as *Archaeopteryx*, were considered to show links between different major groups. The apparent intermediate nature of *Archaeopteryx* by having teeth, as well as derived features of feathers and wishbones, as found in all birds, was used to suggest that birds are descendants of dinosaur-like creatures. No exact sequence of fossils or ancestors could ever be found and it has been known for a long time that no particular group

of fossils could give rise to a particular group of modern taxa. The search for ancestors has gradually switched from reconstructing history sequences of grades in a *scala naturae* to the modern approach of comparing dated fossils in stratigraphic sequences with well-corroborated cladograms (Smith, 1994).

There have been many reconstructions of rates of evolution through geological time in fossil and modern taxa of plants, vertebrates, and invertebrates (see Smith, 1994). The oft cited examples are mammals, particularly horses, from the Eocene to the present, because of their good fossil record (see Panchen, 1992; Simpson, 1951, 1953). In the case of horses, the technique was to see how well morphoclines of characters from the most primitive characters in the oldest taxa gradually changed into the derived characters of modern taxa. These were then examined to see how well these matched the chronocline (the age of fossils as determined by their appearance in the stratigraphic sequence). Simpson's (1951) pioneering work traced lines of descent from the fossil *Eohippus* to *Equus* by creating a linked time series, or *scala naturae*, to measure the rates of morphological changes in skull, forelimb, and upper molar characters in a time period of 60 million years. The approach used was to literally measure the amount of change over a generalized phylogenetic tree after dates were assigned to the horse genera in the sequence (Figure 13). Despite the great

Figure 13 Evolution of fossil horses. Table 1 Differences (distances) in the alpha hemoglobin chains of a selection of vertebrates

	Human	Elephant	Platypus	Ostrich	Starling	Crocodile	Lungfish	Coelacanth	Goldfish	Shark
Human	—	26	40	43	41	47	83	70	68	71
Elephant	18	—	45	45	48	50	84	72	63	74
Platypus	28	32	—	54	52	51	89	74	70	76
Ostrich	30	32	38	—	26	36	91	75	68	73
Starling	29	34	37	18	—	47	91	77	67	70
Crocodile	33	35	36	26	33	—	85	78	70	77
Lungfish	59	59	62	64	64	59	—	90	94	86
Coelacanth	49	51	52	53	54	55	63	—	83	78
Goldfish	48	44	49	48	47	49	66	58	—	88
Shark	50	52	54	52	50	55	63	55	62	—

The alpha chain contains 141 amino acids in most vertebrates, but it contains 142 in the goldfish and the lungfish has 143. Numbers to the upper right half are differences and those in the lower left are percentages. (Reproduced from Table 9.1 in Patterson C (1999) *Evolution*, 2nd ed. London: The Natural History Museum.)

Figure 14 Hemoglobin family tree based on differences between the alpha hemoglobins in Table 1. The two time scales are calibrated from the assumption (based on the earliest known fossils) that sharks, lungfishes, and coelacanths diverged about 400 mybp with 60% amino acid divergence calibrated at 400 myrs. Reproduced with permission from Figure 9.1 in Patterson C (1999) *Evolution*, 2nd ed. London: The Natural History Museum.

effort expended by Simpson, his results give only general approximations on the rates of divergence and the absolute dates are hard to accept because of a lack of a well-corroborated cladogram.

Rates of Molecular Evolution—Hemoglobin

The flood of molecular data accrued since the mid-1960s offers the prospect of more accurate assessments in the calculation of rates of evolution. Absolute rates of molecular evolution have been estimated from branching diagrams by calculating trees from various forms of sequence data and alignment of the cladograms to fossil or biogeographic events

as fixed starting points. By calculating pairwise distances, the minimum ages of cladogenetic events across pairs of taxa can be estimated. These calculations assume that a “clock” is operating within the molecules by gradual and regular substitution of nucleotides or amino acids constantly over time and that the clock can be calibrated to external events (e.g., the age of a fossil), which then reflect accurately the initial cladogenetic events.

Early estimates in the 1960s were made on chains of amino acids and earliest occurrence of fossils to calculate rates of divergence in proteins. Typical results for alpha haemoglobins (Table 1) comparing recent organisms with their fossil relatives suggest that sharks, coelacanths, and lungfishes have hardly changed over 350 million years or more but mammals

Figure 15 A clock-constrained maximum likelihood model mitochondrial DNA tree for mammals. The dates at each node represent millions of years before present (reproduced from Figure 1 in Waddell PJ, Cao Y, Hasegawa M, and Mindell D (1999) Assessing the Cretaceous superordinal divergence times within birds and placental mammals by using whole mitochondrial protein sequences and an extended statistical framework. *Systematic Biology* 48(1): 119–137, with permission from Oxford University Press).

and birds have transformed totally from their fishy ancestors (Patterson, 1999). Patterson showed these calculations indicate that hemoglobin in humans and elephants differ by about 18% as does that of the starling and ostrich. Also, humans and elephants diverged from the ancestral mammals at roughly the same time that ostrich and starling diverged from ancestral birds. In terms of amino acid differences, crocodiles differ from birds by about 33% and mammals by about 35%.

From the rough phylogenetic tree (Figure 14), Patterson calculated from the distance data with a corrected time scale relative rates of amino acid substitution (Table 1). Because there were more than 60% differences in the hemoglobin of sharks, as compared with humans, Patterson corrected for the error of multiple hits, because logically the real number of differences between the different taxa must be greater than those observed. The adjusted divergence times gave 140 myrs for the Platypus/mammal and crocodile/bird splits and about 70 myrs for the elephant/human and ostrich/starling divergence times.

It was from these kinds of results that questions of how natural selection could keep constant rates of divergence through time were asked. One such theory was the Red Queen

Figure 16 A clock-constrained maximum likelihood mitochondrial DNA tree for birds. The dates at each node represent millions of years before present (reproduced from Figure 2 in Waddell PJ, Cao Y, Hasegawa M, and Mindell D (1999) Assessing the Cretaceous superordinal divergence times within birds and placental mammals by using whole mitochondrial protein sequences and an extended statistical framework. *Systematic Biology* 48(1): 119–137, with permission from Oxford University Press).

hypothesis. It takes its name from *Alice in Wonderland* because every species has to keep on running just to keep in the same place. In other words, to compete and to survive all of nature's vicissitudes during the evolutionary changes from shark to human, and between any other pair of species, it is necessary for hemoglobin, and presumably all other features, to adapt at a constant rate (Patterson, 1999).

Rates of Molecular Evolution—DNA

With the advent of nuclear and plastid sequences in the late 1970s and a routine availability of sequences becoming available by the 1990s, it has become increasingly popular to infer divergence time estimates based on nucleotide sequences directly. Through a series of trials and errors it had become obvious by the mid-1990s that single point estimates of divergence times without any assessments of standard error were hardly worth calculating, and some greater degree of sophistication was needed (Waddell *et al.*, 1999). Recent calculations have attempted to improve results by incorporating differential substitution rates for molecular sequence change, a wider range of reliable calibration points based on fossils and other sources of information, and incorporation of standard error values to factors that can be quantified. Waddell *et al.* (1999) applied these techniques to estimate rates using maximum likelihood models and the origins of major lineages of mammals and birds using all available published mitochondrial DNA protein sequences (including unpublished ones for elephants and birds (Figures 15 and 16).

For mammals (Figure 15) the results show that the well-studied horse/rhinoceros split diverged about 55 million years before present. The splitting time among carnivores is confidently shown to be more than 50 million years, and splits within the placentals are relatively old, in the case of armadillo and other mammals 169 mybp but within 2 standard errors of other estimates. Waddell *et al.* reported also that the whale/cow divergence at 65 mybp may be much older than previously assumed. One of the interesting findings is that the sampled splits between the main groups of fereuungulates (carnivores, cetartiodactyls, perissodactyls, and pholidotes) took place prior to the critical Cretaceous/Tertiary boundary. The date of the vicariant separation of Africa and South America is coincident with the age of the cladogenetic event of the armadillo/elephant close relationship at around 122 mybp and could be a causal factor.

The data for birds (Figure 16) was considered more controversial by Waddell *et al.* than for mammals. This was because the deeper calibration points normally used by other researchers between either crocodiles or mammals and birds were considered controversial in their assumptions that rates of evolution in birds had not changed much. They used the fossil anseriform, *Prebyornis*, and placed it with the ducks (geese and swans) using a constraint of anseriform monophyly to have at least one calibration point within birds. Using this information together with more detailed studies of anseriform relationships gave an anseriform stem lineage date of 58–78 (midpoint 68) mybp. The divergence times are indicated in Figure 16. The interesting findings are that the passerines seem to have split off from the rest of the birds at a much earlier date than normally believed and that the divergence time of ratites (rhea and ostrich) is much younger than generally believed.

Conclusions

In an online *Encyclopaedia of Genetics*, Ernst Mayr recently considered cladogenesis and anagenesis as the two great phylogenetic processes of biology. He said that cladogenesis is the study of the origin and of the nature of the branching pattern of the phylogenetic tree. It deals with the various different methods by which the phylogenetic tree is reconstructed. Also, it includes the process of speciation, because every act of speciation adds a branch, no matter how short, to the phylogenetic tree. It is difficult to argue with such points of view because the definitions encapsulate so much of what we know and do in the modern synthesis. They are catchall statements with little or no precision in the contemporary scheme of things. The position taken here is that cladogenesis, and all of its related terminology, sits in some kind of neo-Darwinian time warp, which has become overtaken by huge developments in both systematics and

evolutionary analysis. As Mayr points out, cladogenesis in a very particular sense refers to microevolution and speciation, both topics dealt with elsewhere. In macroevolution the interests are centered around the reconstruction of cladograms and in the discovery of monophyletic groups, topics considered elsewhere in this encyclopedia. In cladistics all effort is concentrated on the patterns of clade distribution and it is generally accepted that grades and branch lengths are of no value in phylogenetic classification but are of interest for determining rates of change. Cladogenesis, anagenesis, and stasis are general descriptors of studies of rates in evolution and extinction, as expressed here in relatively recent calculations of ages of taxa and deeper evolutionary splits. In conclusion, the importance of cladogenesis and related terms have become uncritical in the light of relatively recent studies in systematics; rather they are words in an arcane language largely consigned to the history books.

Glossary

Adaptive landscape A graph of average fitness against the state of the population, represented by allele frequencies or trait means.

Balancing selection Selection which acts to maintain two or more alleles in a stable equilibrium.

Character displacement The displacement of characters caused by competition between species which live in the same place.

Coalescent process The merging of lineages traced backward in time from a sample of genes.

Fitness The total number of offspring produced over one generation.

Frequency-dependent selection Selection in which fitnesses vary with the frequency of different genotypes.

Gene flow The movement of genes from place to place.

Hybrid zone A narrow region in which genetically distinct populations meet, mate, and produce hybrids.

Neutral Having no effect on fitness.

Random genetic drift The random fluctuation in allele frequency caused by random variation in fitness between individuals.

Stabilizing selection Selection on a continuously varying trait toward an intermediate optimum.

Sympatric speciation The separation of a single population living in one place into two species.

Transposable element A DNA sequence which can move from one place in the genome to another.

Introduction

In evolutionary biology, the term differentiation usually refers to the accumulation of genetic differences between populations or species. However, the term can be applied more broadly, to the diversification of genes, organisms, and populations. The extraordinary conservation of the basic genetics and biochemistry across all living organisms implies that life evolved from one most recent common ancestor; the obstacles to the chemical evolution of the first replicator suggests that this ancestor itself evolved from a single origin – most likely, a short self-replicating RNA sequence. Thus, we must explain how past and present biodiversity has differentiated from this simple beginning. We can ask how the first replicating molecules diversified to produce the many kinds of gene in present-day organisms; how the first cells evolved into these diverse organisms; and how populations have come to contain so much genetic diversity. This article sets out to explain how elementary evolutionary and ecological processes lead to differentiation in both the narrow and broad senses.

If we regard species as simply groups of organisms with similar morphology, then the differentiation of populations becomes equivalent to the process of speciation. However, under the biological species concept, speciation consists of the evolution of genetic differences that prevent successful interbreeding; under the phylogenetic species concept, speciation consists of the separation of lineages. Thus, at least in the sexually reproducing populations to which these ideas of species apply, population differentiation is distinct from speciation.

In this article, the author introduces successively more complex processes involved in differentiation. In the simplest kind of evolution, organisms, and populations differentiate under mutation and random reproduction. If there is

inherited variation in the rate of reproduction (i.e., in fitness), then natural selection will shape variation; populations in different environments will become differentiated in a straightforward way. This divergence may be opposed by the flow of genes from place to place, but will only be prevented over the smallest spatial scales. Just as diverse ecological niches are required if species are to coexist, so selection can maintain differentiation within a population only if genotypes exploit different limiting resources. Finally, the author considers how far these genetical and ecological processes can account for differentiation in the broadest sense, and over the largest scales.

Neutral Evolution

Even if all copies of a gene are equivalent, some will by chance leave more descendants than others, leading to random drift of gene frequencies. As we trace their descendant lineages forward in time, some will go extinct, while others will grow in number. Eventually, it is inevitable that one gene will become the ancestor of the entire population (**Figure 1**). Therefore, if we trace the ancestry of all present-day genes backward in time, the lineages will at some point coalesce in a single common ancestor. In an ideal population of N diploid individuals, the chance that any two lineages coalesce is just $1/2N$ per generation. A large sample of genes will take about $2N$ generations to coalesce into two ancestral lineages, and these two will then take, on average, another $2N$ generations to coalesce in one ancestor. Much attention has focused on identifying "mitochondrial Eve," the single female who (assuming strictly maternal inheritance) was the most recent common ancestor of all human mitochondria. The key issue here is when this ancestor lived: a recent Eve would imply a small effective size for the human population.

Figure 1 A sketch of the random reproduction of genes. Moving forward in time (left to right), genes leave random numbers of descendants. Eventually, only one family of descendants survives (in bold). Moving backward in time (right to left), the ancestry of the population takes on average $2N$ generations to coalesce to two lineages, and then the same time, on average, to reach the single common ancestor.

This coalescent process determines the simplest form of differentiation of genes and populations. Suppose that the gene in question consists of a long stretch of DNA, which is always passed on as a unit. Mutations will occur at a rate μ , at random times and at random sites in the sequence; to a good approximation, mutations never occur at the same site twice (the infinite sites model). If we examine sequences which shared an ancestor a time T in the past, they will on average differ by $2\mu T$ mutations. If these gene sequences come from two well-separated species, then we can date the divergence of those species by the steady ticking of a molecular clock. Indeed, it was the striking observation that any given protein accumulates mutations at a steady rate that stimulated Kimura to develop the neutral theory of molecular evolution. Across a range of eukaryote lineages, sequences which have no effect on fitness mutate and diverge at a rate of $\sim 10^{-8}$ per base pair per year.

Variation within a population can be understood in a similar way. If two gene sequences are chosen at random, they will share an ancestor on average $T = 2N$ generations back; therefore, they will differ by, on average, $4N\mu$ mutations. This simple prediction is in qualitative agreement with observations on molecular genetic diversity within populations. However, variation in extremely large populations is not vastly greater than in much less abundant species: For example, about 5% of enzyme loci in humans are heterozygous, while about 25% are heterozygous in the bacterium *Escherichia coli*. There are two possible explanations for the weak relation between within-population diversity and census numbers. First, the effective population size may be much smaller than the actual census number, because of occasional bottlenecks and local extinctions, or because of selection on linked genes. For example, in *Drosophila melanogaster*, $\sim 1\%$ of noncoding base pairs are heterozygous, which, with $\mu = 10^{-8}$ per base per

Figure 2 An example of the clustered pattern produced by random reproduction. Each dot represents an asexual organism, or a separate species. The position of each point represents its morphology, reduced to two dimensions; this evolves in a random walk, following a normal distribution. Each lineage goes extinct with constant probability, and splits at a rate which decreases with the total number of lineages. The open circle represents the ancestor.

year, implies that a random pair of bases share a common ancestor $T \sim 0.01/2\mu = 5 \times 10^5$ years back. Assuming 4 generations per year, this implies an effective population number of $\sim 10^6$ flies – many fewer than the census number. Second, variation in coding and regulatory regions of the DNA may be maintained by selection, regardless of population size.

Neutral evolution does not lead to a homogeneous pattern of differentiation. Imagine that a process of random reproduction produces lineages as in **Figure 1**. (We might think of asexual organisms, or of species originating and going extinct.) If morphology changes by random increments, then the variance amongst a group reflects the age of that group. Now, random genealogies typically have a hierarchical structure, with most family groups being closely related compared with the age of the whole. Morphology is therefore expected to fall into well-separated clusters (**Figure 2**). Of course, the clustering that we see in the living world, which allows us to classify organisms into species, genera, and higher taxa, is not merely due to random reproduction. However, it is important to realize that what Darwin termed "descent with modification" tends naturally to produce clusters of distinct morphologies.

The recent availability of DNA-based markers, which for the most part can be presumed to have negligible effects on fitness, has transformed evolutionary biology. These provide a molecular clock against which to measure divergence times; an objective and quantitative means of reconstructing phylogeny; and a baseline level of differentiation within and between populations, against which to measure other processes. Having established this straightforward benchmark, we can consider how selection, gene flow, and ecological interactions influence differentiation.

Natural Selection

A difference in relative fitness of s (the selection coefficient) causes change over a time $\sim 1/(1, s)$; it dominates over random genetic drift if $s > 1/N$, and over mutation if $s > \mu$. Thus, even slight fitness differences of $s > 10^{-5}$ will be the predominant force in a population of effective size larger than 10^5 individuals, and for genes consisting of (say) 10^3 base pairs, each with mutation rate 10^{-8} per generation. Such minute fitness differences cannot be measured directly. However, a multitude of studies show that selection on morphological traits and on individual genes can be strong ($s > 10\%$, say). Nevertheless, we will see that this does not imply that differentiation among populations is a simple consequence of selection alone.

In this section, the author considers the straightforward effects of selection in the simplest case, where each genotype (i.e., each set of genes) has a fixed effect on fitness. Variation within populations is then maintained by a balance between mutation generating deleterious variants, and selection eliminating them. (For the moment, we leave aside cases in which heterozygotes are fitter than either homozygote.) While mutation rates on individual bases are extremely low, the net mutation rate over the whole genome may be high, and so may sustain substantial genetic variation. For example, Eyre-Walker and Keightley (1999) used rates of DNA sequence divergence among primates to show that the human lineage has been subject to roughly one deleterious mutation per genome per generation. At the level of the whole organism, the variance of continuous traits such as growth rate or skeletal proportions increases by roughly 0.1% every generation as a result of new mutations; thus, much of the response to long-term artificial selection is due to mutation, rather than to standing variation. The genetic basis of such mutations is beginning to be understood. For example, Lai *et al.* (1994) found that $\sim 10\%$ of the variance in bristle number in a natural population of *D. melanogaster* was due to the insertion of transposable elements around the *scabrous* gene; these insertions are clearly deleterious, since they were all found to be of relatively recent origin, and hence rapidly eliminated by selection.

There is a long-standing debate over the processes which maintain genetic variation. While this is as yet unresolved, it is at least plausible that most variation, in both discrete genes and continuous traits, is due to deleterious mutations. On this view, differentiation within populations is merely a fluctuation around some optimal state, while differentiation between populations is a direct consequence of changes in that optimum. The ability of artificial selection to rapidly change almost any aspect of an organism was Darwin's strongest argument for the efficacy of natural selection, and remains so today. Almost all traits show heritable variation, and therefore respond to selection; what is remarkable is that this response continues apparently without limit (at least, over the span of human experiments). For example, Weber (1992) selected on the angle between two small veins on *Drosophila* wings. Lines selected in opposite directions diverged steadily, and differed by 20 standard deviations after 15 generations. We now understand that at the genetic level, this divergence is due to the establishment of individual alleles, either present in the

original base population, or generated by new mutations. Weber's lines, for example, differed by at least 11 genes on one chromosome, each of small effect.

There has been much dispute over whether adaptive differences between populations and species are due to the accumulation of minute differences, or to a few genes of large effect. Darwin emphasized the former view, on the grounds that complex and finely adjusted adaptations could only be built up by slight variations. In contrast, the geneticists who rediscovered Mendelian heredity emphasized the importance of major mutations. After a century of research, the answer is only beginning to become clear. On the one hand, sustained, steady responses to selection must be based on multiple genes of small effect, and genetic analysis of species differences usually shows that many genes are involved in maintaining their separation. On the other hand, differentiation in particular traits is often based on one or a few genes. Insecticide resistance usually evolves through mutations in particular target genes (e.g., in the acetyl cholinesterase enzyme that is the target of organophosphates). To take a natural example, the striking differences between warning color patterns of *Heliconius* butterflies are due to only a handful of genes (Counterman *et al.*, 2010). Much effort is now being devoted to identification of the quantitative trait loci responsible for human variation related to disease, for differences between varieties of domesticated plants and animals, and for adaptive differences between species. Such methods do often identify genes of major effect: indeed, the whole enterprise of genetic engineering rests on the possibility of obtaining useful results by manipulating a few key genes. However, there is a statistical bias toward finding genes of large effect, and recent large-scale studies of human height suggest that heritable variation depends on a very large number of alleles of small effect (Yang *et al.*, 2010).

Given that selection can rapidly adapt populations to changing conditions, and given that selection is often the strongest evolutionary force, one might suppose that differentiation would simply reflect the optimal genotype which is favored by the local environment. We could then say rather little about what patterns of differentiation to expect, since they would be the outcome of the particular interactions between organism and environment that determine reproductive success. However, matters are not so simple. There may be alternative combinations of genes which are locally optimal, and so populations may adapt to essentially the same conditions in different ways. Sewall Wright devised an influential way of thinking about this issue, the "adaptive landscape" (Figure 3). This is a surface which represents the average fitness of a population, plotted against a set of axes which describe the state of a population (e.g., gene frequencies or trait means). Under the simple assumptions of this section, natural selection pushes populations uphill on this landscape, toward a local "adaptive peak." In general, there will be many such peaks, and so populations will differentiate under selection even if they all experience the same environment.

Divergence may be observable at the phenotypic level, or may be cryptic. For example, suppose that a trait is determined as the sum of effects of many genes, each carrying either "+" or "-" alleles. If selection favors a single intermediate optimum, any combination of genes that achieves that optimum

Figure 3 A simple “adaptive landscape” for two loci, each carrying two alleles. One allele at each locus is dominant, with frequency denoted by p_1 and p_2 . The double dominant (P1P2) and double recessive (Q1Q2) genotypes are assumed to be most fit, with $W_{PP} = 1$, $W_{QQ} = 0.8$, $W_{PQ} = 0.4$, and $W_{QP} = 0.2$.

can be established (+ + - -, - - + +, ...). Such cryptic divergence is revealed when crosses between populations produce progeny with reduced fitness and increased variance; over the largest scales, it is reflected by sibling species, which are morphologically indistinguishable and yet reproductively incompatible.

Divergence toward alternative “adaptive peaks” can occur in several ways. Random genetic drift in small populations may knock populations into the domain of attraction of different peaks. This process is especially likely if there are flat ridges on the adaptive landscape along which divergence is not opposed by natural selection. For example, if only the double recessive homozygote $P_1P_1P_2P_2$ is unfit, then populations initially containing Q_1 and Q_2 can fix either P_1 or P_2 , with no effect on fitness. However, when crossed they have reduced fitness. Genetic analysis of hybrid inviability and sterility in *Drosophila* show that incompatibilities are largely recessive, which supports this model of quasi-neutral divergence. A different line of evidence comes from studies of functional RNA molecules (e.g., the transfer RNAs that translate the genetic code). Many changes in individual bases cause no appreciable change in three-dimensional structure, so that extensive divergence can occur without disruption of function.

Random processes can drive divergence even in large populations. If adaptation depends on new mutations, then different mutations may arise first in different places. For example, humans have evolved resistance to malaria by a variety of different mutations in the β -hemoglobin molecule: the S allele in Africa, the C allele in Asia, and various thalassemias in

the Mediterranean. These alternative alleles tend to exclude each other, so that chance differences in first occurrence of mutations leads to permanent divergence. Finally, divergence may be driven by fluctuations in selection. Suppose that the “adaptive landscape” fluctuates as conditions change, but maintains overall distinct peaks. Then, populations may end up on different peaks, even if they experience the same mix of environments: the outcome depends on the particular sequence of environments which they encounter.

While the “adaptive landscape” is a helpful metaphor, it gives a misleading picture of the geometry of evolution. Evolution can proceed in very many dimensions, rather than just the few which can be visualized by the human mind. This dimensionality is nicely illustrated by the model experiments of Eigen and co-workers, in which RNA molecules ~ 100 bases long are replicated by a polymerase derived from the Q β virus. Under given conditions, some definite sequence (and its mutational variants) is picked out by selection from amongst $4^{100} - 10^{60}$ possibilities. This is possible because any sequence is connected to any other by no more than 100 mutational steps. At any stage, 300 variants are available from a single mutation, since each base can mutate to three alternatives. Provided that there is some sequence of steps which leads uphill toward the optimal sequence, selection will effectively search from amongst the astronomical numbers of possibilities. This multidimensional view emphasizes that the outcome depends on which mutations are available: while evolution could take any of a large number of directions at any stage, this number is very much smaller than the total space of possibilities, and sets a strong constraint.

Gene Flow

The most obvious impediment to differentiation is gene flow: that is, the mixing of genes from different populations caused by movement of the individuals that carry them. At least since the mid-nineteenth century, there has been controversy over whether such mixing prevents differentiation. Darwin held that populations could adapt to gradually varying conditions across their range and that this could lead to the origin of new species. In contrast, Wagner emphasized the importance of barriers to migration as prerequisites for speciation. This view has been strongly propounded in more recent years by Ernst Mayr. However, both population genetic theory, and observations of geographic divergence, strongly support the Darwinian view, at least if one considers adaptations which can be built up by individual alleles or by continuous changes in quantitative traits.

Gene flow has straightforward and well-understood effects. The rate of gene flow into a single population is measured by m , the fraction of genes derived by immigration in each generation. Mixing then occurs over a timescale $\sim 1/m$. In a broadly continuous habitat, gene flow can be well approximated as a diffusion: in the same way that gas molecules diffuse as a result of random collisions, so genes diffuse through their habitat as a result of the random movement of the organisms that carry them. The rate of diffusion is measured by σ^2 , the variance of distance between parent and offspring along any particular axis. Over a time T , this diffusion causes genes to spread over a distance $\sim \sqrt{(2\pi\sigma^2 T)}$. For example, the annual grasshopper *Chorthippus parallelus* is divided into two subspecies *C. p. parallelus* and *Chorthippus p. erythropus*, which met in the Pyrenees after the past Ice Age, $\sim 10^4$ years ago. These grasshoppers move by about 30 m in a year, so that $\sigma^2 \sim 900 \text{ m}^2$ per year. Enzymes which are fixed for different alleles in the two subspecies mix over a region $\sim 15 \text{ km}$ wide, which is of the same order as the distance predicted by simple diffusion, $\sqrt{(2\pi\sigma^2 T)} \sim 7.5 \text{ km}$ (Hewitt, in Harrison, 1993).

Whether populations can adapt to local conditions, despite mixing, depends essentially on the relative rates of gene flow and selection. An allele with selective advantage s in the heterozygote can be established in a single population despite gene flow, provided that the rate of immigration of individuals carrying the alternative allele is lower than the rate of selection ($m < s$). If genes diffuse across a continuous habitat, then an allele can become established provided that it is favored in a region larger than some critical distance proportional to the characteristic scale $\sigma/\sqrt{s}$. New mutations have a chance of fixation approaching $2s$ if they arise within the appropriate region, but the probability falls to zero outside this region. Similar considerations apply to adaptations based on continuously varying traits. Suppose that fitness falls away in a Gaussian function with variance V_s (i.e., stabilizing selection); the optimal trait value varies from place to place. The characteristic scale over which populations can respond to local conditions is now $\sigma\sqrt{(V_s/V_g)}$, where V_s is a measure of the strength of stabilizing selection, and V_g is the additive genetic variance.

Since the dispersal range σ is typically much smaller than the species' range, these theoretical considerations imply that

weak selection can allow a species to adapt to diverse local conditions. This can be seen directly. For example, the grass *Agrostis tenuis* has evolved tolerance to heavy metals on mines only a few meters across. Similarly, narrow clines $\sim 10 \text{ km}$ wide, separate races of *Heliconius* butterflies which carry alternative warning color patterns (Mallet, in Harrison, 1993). Such examples leave little doubt that gene flow need not prevent divergence over very short scales.

If variation in selection can cause differentiation over local scales, why do species not fall apart into a myriad of separate forms? Mayr was led to argue that gene flow prevents differentiation of populations by his observation that species remain morphologically homogeneous over much of their contiguous range: it is this homogeneity that makes taxonomy practicable. How can we explain this apparent conflict with the potential power of selection to cause differentiation?

Much variation in protein or DNA sequence may have such small effects on fitness that selection is negligible relative to gene flow. Such neutral variation will differentiate as a result of random genetic drift. However, because drift is weak in even moderately abundant populations, weak gene flow homogenizes neutral variation. In a single population, the number of migrants, N_m , is crucial. The variance of allele frequency within the local population is $\bar{p}(1-\bar{p})/(1+4N_m)$, where $\bar{p}$ is the allele frequency in the source population; hence, if more than one migrant per generation enters, there will be little differentiation. This result carries over to populations spread over two dimensions, either in an array of subpopulations, or in a continuous habitat. (In the latter case, the crucial parameter is $\rho\sigma^2$, where ρ is the population density.) The effectiveness of gene flow in overcoming random drift has an important consequence: even if selection within local populations is ineffective relative to drift ($N_s \ll 1$), the cumulative effect of selection across the whole population of N_{tot} individuals dominates if $N_{\text{tot}}s > 1$. For many purposes, a population with $N_m > 1$ can be treated as a single gene pool.

Many surveys have been made of geographic variation in gene frequency, using both protein and DNA variation. The usual finding is that the variance in allele frequency between locations is small ($\rho/\bar{p}(1-\bar{p}) < 5\%$; this ratio is termed F_{ST}), implying that if this variance is at an equilibrium between random drift and gene flow, the number of migrants is large ($N_m > 5$). There are of course exceptions: for example, the salamander *Ensatina eschscholtzii* has exceptionally low dispersal, and correspondingly, $F_{ST} \sim 0.7$ (Wake and Yanev, 1986). However, the general conclusion is that gene flow is sufficient to homogenize differentiation generated by random drift.

Surveys of geographic variation often aim at estimating the number of migrants (N_m). However, even if large-scale differentiation is generated by random drift, its geographic pattern may be dominated by past history, rather than by present-day rates of gene flow (see Whitlock and McCauley, 1998). If a species is extinguished from a large region (as happened in temperate regions during the Ice Ages), and then reinvades, the pattern of variation reflects the pattern of recolonization. In European human populations, Cavalli-Sforza and co-workers have reconstructed the history of population movements from the detailed genetic data that are available: many loci show traces of the introduction of distinct alleles as agriculture spread from the Near East. When the genealogical

relationships amongst DNA sequences can be inferred, historical events can be seen more directly. For example, *Awise* (1994) has identified in many species a cryptic subdivision which runs across the south-western United States; this is a relict of a separation into different Pleistocene refugia. Such reconstructions should be based on several unlinked genetic loci, however: within a sexual species, different loci may have different histories.

Much molecular differentiation may have slight effects on fitness, allowing it to be used to reconstruct the history of gene movements. However, we cannot explain the apparent homogeneity of species simply by an absence of selection. There are many examples of geographic variation at enzyme loci which are maintained by selection for adaptation to different environments. Evidence of selection may come from direct measurement, from close correlation with environment, or from discordance in pattern between different loci. (For example, the geographic pattern at several enzymes in European humans differs significantly from the majority of genes, whose pattern reflects population history.) Morphological traits are usually strongly selected, and so their geographic patterns therefore do not match those predicted from putatively neutral markers. Because selection can cause rapid divergence, even in the face of gene flow, extinctions and recolonizations can only generate a transient homogeneity in selected traits. Thus, we expect to see morphological patterns which follow recent selection imposed by environmental features, and cut across patterns at neutral markers which reflect population history. For example, *Schneider et al.* (1999) found that in the skinks of north-eastern Australia, mitochondrial DNA and microsatellite markers tend to change along the Black Mountain Corridor, a biogeographic feature marking past range changes. In contrast, skeletal morphology changes in a quite different pattern, which parallels the transition from open to closed forest.

The evident power of selection to cause divergence remains hard to reconcile with the apparent similarity of species across large areas which Mayr and others have emphasized. The problem is close to that posed by examples of stasis in the fossil record, in which morphology remains similar over long times rather than large distances. One possibility is that in sexual species, different traits or genes can evolve independent spatial patterns, so that overall morphology is more stable than any one component, and varies more smoothly. In any case, the supposed homogeneity may be exaggerated. Sharp transitions ("hybrid zones") do often occur, prompting classification of the taxa on either side as species or subspecies. These may arise either when many traits respond to a sharp environmental discontinuity (as in the skink example, above), or when populations that have diverged to become partially incompatible are brought together by a range expansion. In the latter case, divergence remains permanently because the hybridizing populations are at two different "adaptive peaks."

Ecological Differentiation

A simple form of natural selection, in which each gene combination has a fixed fitness, can explain much of evolution: it accounts for differentiation between populations and species

as a result of changing conditions, mutation, and random drift, and despite gene flow. However, at the very least absolute fitness (i.e., the number of offspring) must decrease with density if the population is to remain bounded. We expect the relative fitnesses of different genotypes to change with their abundance in the population: selection is in general frequency-dependent. If the reproductive success of an allele decreases as it becomes more common, then genetic diversity can be maintained. This is known as balancing selection.

Maintenance of genetic diversity by frequency-dependent selection arises from competition for different limiting resources, in just the same way as maintenance of species diversity. If the concept of a "limiting resource" is interpreted broadly, then all examples of balancing selection can be seen in this way. Evidence for a heterogeneity of resources, cited by Darwin and exploited by plant breeders, comes from the increased yield of a mixture of varieties compared with a pure stand. Here, the limiting resources may consist of different nutrients, though other mechanisms are possible. A classic example of frequency-dependent selection is Batesian mimicry, in which a palatable species avoids predation by mimicking a distasteful model species. As the mimic becomes common, predators fail to associate their pattern with unpalatability, and protection is lost. Batesian mimics such as swallowtail butterflies therefore evolve diverse mimetic patterns, each of which remains rare. The limiting resources here are the various different model species. In diploid species, variation can be maintained by heterozygote advantage. The classic example is the polymorphism for the β -hemoglobin S allele, where the heterozygote gains resistance to malaria, while the homozygote suffers from sickle-cell anemia. The relative fitnesses of diploid individuals are fixed, but from the gene's point of view, fitness decreases with frequency: a common allele is more likely to find itself in a homozygote. The limiting resources here are the two kinds of allele with which each gene can find itself paired in a diploid.

The existence of heterogeneous limiting resources is, in a broad sense, necessary for maintaining diverse species, and may be responsible for much genetic differentiation within species. However, we do not know how much genetic variation is maintained by balancing selection, as opposed to mutation and gene flow, and we do not know how far organisms respond to environmental heterogeneity by evolving diverse genotypes or diverse species. A trade-off between variation within and between species is revealed by character displacement, where coexisting species tend to diverge in morphology and behavior. The *Anolis* lizards of the Caribbean provide a classic example. Where one species lives on an island, it has a broad distribution of body size; where two species share an island, they take up nonoverlapping distributions, and so partition the available prey. A similar phenomenon can be seen where asexual clones compete with their sexually reproducing relatives. The freshwater fish *Poeciliopsis monacha* and *Poeciliopsis lucida* occasionally mate, and produce a parthenogenetically reproducing clone. *Vrijenhoek* (1994) found that in streams with many different asexual clones, there tend to be fewer of the sexual progenitor species. This suggests that the space of available ecological niches can be filled either by a set of distinct asexual clones, or by members of the genetically diverse sexual population.

If multiple forms, each exploiting a different resource, coexist in a sexual population, then matings between them may produce maladapted progeny. To make this point in another way, imagine that resource use depends on a set of continuously varying traits. If these traits are determined as the sum of effects of several genes, then sexual reproduction produces an approximately normal trait distribution. There is no reason why this should match the distribution of resources which are available. The problem can be avoided if the genetic system can somehow produce the appropriate distribution despite the random shuffling of genes that occurs with sexual reproduction. For example, swallowtail butterflies produce many distinct wing patterns, each mimicking a different distasteful model. These are determined by several genes, which are so tightly linked that they behave as a single genetic locus. If such genetic tricks do not evolve, then selection favors mating behaviors that causes like to mate with like. Ultimately, such selection could lead to complete reproductive isolation between the two forms. This splitting of a single population into two separate species in the absence of spatial separation is termed sympatric speciation. It is almost impossible to demonstrate directly, since any present pattern of divergence might have originated with some spatial isolation. However, there are several plausible cases. For example, several distinct morphs of cichlid fishes have evolved within isolated crater lakes (Schliewen *et al.*, 2001). A key question is how often ecological differentiation amongst genotypes evolves into differentiation between species in this way.

Darwin emphasized that natural selection is driven by competition for limited resources (the “struggle for existence”). Moreover, he argued that the lack of intermediate forms – the evident clustering of organisms that makes taxonomy possible – can be explained largely by the diversifying effects of competition. There is a “division of labor” amongst organisms, which (as with market economics) results from competition between individuals rather than any optimization of species’ or community productivity. Similar processes account for the differentiation of the $\sim 10^5$ different genes in complex organisms. Often, one gene may acquire multiple functions. For example, arginosuccinate lyase in birds acts as a lens crystallin as well as having a catalytic function. Similarly, most of the genes responsible for the establishment of segmentation in early *Drosophila* development are also involved much later in specifying various organs. If by chance a multifunctional gene duplicates, then each copy may specialize to become more efficient at one of the two original functions. The sequencing of complete genomes has made clear the extent of gene duplication and differentiation: most yeast genes are members of closely related families. There are close analogies between the division of labor among different species within an ecological community, different genotypes within a population, and different genes within an organism.

Evolution Over Large Scales

The processes of selection, mutation and random drift that lead to differentiation are well understood, at least over the

short timescales that are accessible to experiment and observation. How far do they account for the differentiation of genes and organisms over the whole span of evolution? First, consider the overall pattern. The first fossil evidence of complex multicellular organisms is found in the Ediacaran fauna, about 560 million years ago. An extraordinary diversity of animals with skeletons evolved soon after, at the beginning of the Cambrian, and included representatives of almost all present animal phyla. Molecular evidence suggests that the ancestral lineages of these phyla may trace back much further; nevertheless, there was a rapid diversification of body plans during this “Cambrian explosion.” The subsequent fossil record shows an overall increase in diversity, as measured by numbers of species, but interspersed with occasional mass extinctions. Organismal complexity is hard to quantify, and trends in complexity are controversial: while the most complex organisms may become more complex as diversity increases, it is not clear that there is (or should be) any trend toward more elaborate organisms. Rates of morphological evolution can be quantified more readily, at least for hard parts. Morphology changes much more slowly over the long timespan of the geological record than in current populations (Gingerich, 1983). Only weak selection pressures need be invoked to explain observed rates, and indeed, it is surprising that morphology has often changed little over millions of years.

If we suppose that organisms differentiate primarily as a result of selection to fill different ecological niches (more precisely, to exploit different limiting resources), then we might imagine that these macroevolutionary patterns could be explained by diversification to fill a set number of preexisting niches. At equilibrium, there might be a balance between extinction and species formation, leaving many niches unfilled; nevertheless, diversity of species and their morphology would be expected to rise toward some definite value. This view is supported by statistical analysis of the fossil record, which suggests saturation of species numbers. Over shorter timescales, remote islands such as the Hawaiian archipelago are occupied by the descendants of a few colonizing species, which radiated to fill the roles normally occupied by other taxa. However, new organisms generate new niches. One host species is often plagued by several specialist parasites, which are restricted to that host by specific adaptations to evade its defenses. The evolution of novel features (multicellularity, bony skeletons, flight, etc.) are followed by a rapid diversification into novel ways of living. While the maintenance of diverse genotypes and species can be understood formally in terms of competition for distinct limiting resources, their number is not fixed, and seems inherently unpredictable.

The pattern of diversity that we see may not be entirely a matter of historical accident. Even though there is no difficulty in explaining the rapid evolution of any one gene or trait, there are fundamental limits on the numbers of genes, the rates at which new genes are substituted for old, and the number of different genotypes that can be maintained within a population. The total mutation rate cannot greatly exceed one per generation, since most mutations are deleterious, and each deleterious mutation requires roughly one selective death to be eliminated. The human mutation rate approaches this upper limit, which may limit the number of functional genes

that we carry. Each substitution of one allele by another requires that individuals carrying that allele leave more offspring than those that do not: Haldane (1957) showed that this implies a “cost of natural selection” which limits the rate at which new alleles are substituted. Again, this argument places a strong constraint on the number of adaptive changes that can have occurred during human evolution. Finally, the diversity that can be maintained within a finite population is limited: the maximum number of genes that vary independently can be no greater than the effective population size. These constraints give some hope that we can understand the overall features of organismal differentiation, even if the detailed pattern is a conglomeration of unique historical events.

Glossary

Background selection Selection that takes place at loci other than that of interest. Such events can strongly increase the intensity of genetic drift as well as hinder the action of selection at a locus of interest. These effects are normally modeled by reducing the effective population size applicable to the locus of interest.

Divergence A fixed genetic difference between two species or populations, or the process of evolving such a difference.

Effective population size The size that a random mating population must have to experience the same intensity of genetic drift as a population of interest. The size can vary across genes due to changes in background selection across the genome.

Functional constraint A limit to the kinds of mutations that can appear in a gene or protein without compromising function, often also called “selective” constraints.

Genetic drift Random changes in gene frequency that occur when a finite number of zygotes or propagules is formed by random sampling gametes or genotypes from the previous generation to create the next generation.

Mutation A change in the nucleotide sequence of a DNA or RNA molecule.

Nearly neutral mutation A mutation whose population genetic dynamics are influenced by both genetic drift and selection.

Neutral mutation A mutation whose population genetic dynamics are influenced only by genetic drift.

Nonsynonymous mutation A nucleotide change in a protein coding region that changes the encoded amino acid.

Polymorphism A genetic difference between two or more individuals of the same species; to exclude new mutations from the definition, the underlying mutations are required to segregate above an arbitrarily set minimal frequency (1% or 5%).

Replacement Divergence due to a change of an amino acid in a protein, or the process to evolve such a change.

Selection Differential reproduction within a set of genes, individuals, groups, etc. caused by differential performance in fitness determining tasks. The appropriate unit of selection (gene, individual, group) is determined by the level at which the causation of the fitness differences must be described (interactions or performances at the level of genes, individuals, groups, etc.).

Substitution Divergence due to a change of base in a DNA sequence, or the process of evolving such a change.

Synonymous mutation A nucleotide change in a protein coding region that does not change the encoded amino acid.

Understanding the population genetic mechanisms that generate molecular diversity is fundamental to understanding how biodiversity is maintained and generated. This article deals with molecular diversity at the DNA and protein levels, and concentrates on diversity that is genetically heritable. We will discuss molecular diversity patterning and causation primarily at the level of single genes and genomic regions. Therefore, important aspects of molecular diversity that concern higher level genomic structuring and evolution will not be mentioned (e.g., genome size evolution, gene duplication, and gene family evolution). The article will deal first with DNA and protein diversity within species (molecular polymorphism) and then with diversity generated by genetic differentiation between species (molecular divergence). Such order is justified because visualizing diversity in this way helps understanding the evolutionary and population genetic forces and processes that generate it.

The information presented here is almost exclusively drawn from knowledge gathered by molecular population geneticists and molecular evolutionary biologists. Molecular population genetics studies the form and extent of molecular polymorphism, and tries to identify the forces that pattern it. Molecular evolutionary research aims at characterizing the degree and forms of molecular divergence, at clarifying how

such differentiation takes place, and – by taking advantage of the former – at reconstructing the history of DNA sequences and proteins and the genealogical relationships among extant and sometimes extinct organisms.

Introduction

Phenotypic differences between organisms are due to genetic and environmental differences, and the former are the result of genetic divergence or polymorphism. Realizing that polymorphism is a common and striking phenomenon in the living world is not only important when trying to make sense of molecular diversity. Indeed, the transition from typological (essentialistic) to variational–populational thinking was a major contribution of the Darwinian revolution to biology.

Measuring genetic diversity within and between species is a long-standing interest of biologists. However, this only became possible in a systematic way in the 1960s when novel techniques from molecular biology (protein sequencing and enzyme electrophoresis) began to be applied to the study of evolutionary and population genetic questions. These techniques opened the possibility to study variation at the molecular level (amino acid sequence divergence and allozyme variation)

and gave birth to the fields of molecular evolution and molecular population genetics. The availability of protein sequences from various taxa triggered sophisticated studies of the forces driving protein evolution and led to the first reconstructions of historical relationships among organisms using protein sequence data (molecular phylogenetics). However, protein sequencing could not be used for quantitatively oriented studies of polymorphism because of its laboriousness. Electrophoretic studies of variation were carried out in hundreds of taxa uncovering the presence of large amounts of genetic variation in natural populations, although levels of molecular variation were mostly underestimated due to methodological limitations.

The advent of DNA sequencing in the 1980s improved resolution and made it possible to describe exhaustively the genetic variation segregating at single loci. Before DNA studies this was not possible, and in fact investigators developed and tested models that predicted patterns for electrophoretic variation segregating at many loci, because only such data could be produced in statistically analyzable counts. The shift to DNA studies allowed researchers to quantify conclusively not only amino acid polymorphism but also coding region variation that does not change the encoded amino acids (synonymous variation) and variation in noncoding regions, both of which were found to occur in copious amounts. This increased drastically the amount of data obtainable from a single locus and thus the number and the statistical quality of contrasts among classes of variation subject to arguably different functional constraints. New methods were developed to describe the processes shaping DNA level variation within and between populations and new, often more powerful, modeling approaches were developed and/or given a more solid empirical grounding (e.g., coalescence and maximum likelihood estimation of genetic distances). More recently, developments in DNA sequence technology have allowed fast and cheap genome sequencing, allowing researchers to obtain large-scale, and more precise, estimates of polymorphism and divergence for a wide variety of species. Unfortunately, despite all the technical and conceptual advances in quantifying and interpreting patterns of molecular variation, we still know very little about the genetic basis of adaptation and about the relationship between genetic and phenotypic differences among organisms.

The Generation and Maintenance of Genetic Diversity

There are three main sources of genetic variation in natural populations: mutation, recombination, and migration. Mutation is the only mechanism that can generate variation in a genetically homogeneous population, since recombination and migration only shuffle and shuttle around preexisting variation, respectively. Mutation is therefore the original source of all genetic variation.

To understand the evolutionary and population genetic forces patterning genetic variation, it is useful to consider variation at two main levels: within and between species. The first level constitutes the polymorphism component of genetic diversity, which can be also considered at finer levels if gene flow is structured within the species under study ("geographic" structure). Within sexual populations this type

of diversity more or less freely combined each generation to form individual genotypes. The second level constitutes the divergence component of genetic diversity, which can also be considered at multiple levels depending on how closely related the species under study are. This type of diversity consists of fixed differences between species and is only exchanged under special circumstances (horizontal gene transfer, introgression).

The patterns of genetic variation within species arise from the combined action of two main set of processes: (1) a molecular-level origination process in which a mutation in a DNA sequence arises and (2) a population-level "fate" process that determines whether the mutation is quickly eliminated from the population or enters the pool of intraspecific variation becoming a polymorphism. The fate process also includes the possibility that the mutation becomes fixed in the population and thus becomes part of the divergence component of diversity. If a new mutation is passed on to the next generation of individuals, its final fate depends on the stochastic error produced when creating a finite number of zygotes or propagules by sampling gametes or genotypes from the previous generation (random genetic drift), on demographic forces like changes in population size and gene flow, as well as on the deterministic action of natural selection if the mutation is deleterious or advantageous.

Diversity as Polymorphism

What is the quantity (and quality) of genetic variation found in natural populations? What are the evolutionary forces responsible for the observed patterns of variation in natural populations? What is the meaning of that variation? What is the relationship between adaptive changes, phenotypic changes, and extant genetic variation? These are some of the questions asked by evolutionary geneticists. This section will give examples and summarize the current answers to the first two questions, but will not elaborate on the last two given the inconclusiveness of the current knowledge on the subject.

The Mutation Process: Molecular Biological Considerations

The mutation process is known to be affected by physiological and life history characteristics of the organism that affect the rate and accuracy of DNA replication (generation time, number of divisions before gametogenesis, sex, age) and by factors that increase damage to DNA (metabolic rate, age, transcription rate, frequency, and degree of packing and unpacking of chromosomes for expression). Exogenous agents that can damage DNA include UV light, ionizing radiation from X-rays, heat, alkylating agents, and hydroxyl radicals originated by the interaction of ionizing radiation with water. Endogenous agents include oxidant by-products of normal metabolism. Changes generated by endogenous agents cause the highest fraction of DNA damage. In human cells, oxidants damage between 10^4 and 10^5 nucleotide sites every day. Such damage would be extremely deleterious were it not for the presence of enzymes involved in finding and repairing it.

Of the five major types of DNA mutations – substitutions, deletions, insertions, inversions, and duplications – nucleotide substitutions and single base pair deletions or insertions (all called point mutations) account for 85% of the mutation events. With the exception of macromolecular events like chromosomal rearrangements, most mutations are the result of errors made by enzymes involved in DNA replication and

repair. Replication errors are often due to the incorporation of noncomplementary nucleotides by the DNA polymerase and incorrect subsequent proofreading by the same enzyme. The latter process, however, is normally extremely effective in lowering the error rate by a millionfold relative to the intrinsic misincorporation rate of the polymerase.

Estimating the rate at which spontaneous mutations arise is challenging but constitutes a very important aspect of evolutionary studies. In the past, genome-wide mutation rates were extrapolated from indirect measures at single or few loci using experimental (e.g., mutation accumulation lines and reporter constructs) or evolutionary approaches (e.g., using patterns of sequence divergence among species). Due to the recent development of high-throughput methods to sequence complete genomes, precise estimates of genome-wide mutation rates have been obtained for five eukaryotes (Table 1). A recent analysis that includes a wide variety of organisms suggests that mutation rate is inversely correlated with genome size in viruses and prokaryotes, although this correlation is extremely weak. However, mutation rate is strongly and positively correlated with genome size in unicellular and multicellular eukaryotes (Figure 1(b)). Those differences in the fidelity of DNA replication across organisms with different genome size may be explained by the interplay of natural selection and population size, given the negative correlation between inferred effective population sizes and genome size (Figure 1(a)): selection to lower the mutation rate is more efficient in organisms with large effective population sizes (which have smaller genome sizes), whereas in organisms with smaller population size (and higher genome size) genetic drift becomes a limiting factor on how much selection can drive mutation rates to lower levels.

Table 1 Direct estimates of the genome-wide mutation rate in five eukaryotes using whole genome sequencing

Organism	Mutation rate per base pair/generation (genome size)
<i>Saccharomyces cerevisiae</i> ^a	0.33×10^{-9} (13 Mb)
<i>Caenorhabditis elegans</i> ^b	2.7×10^{-9} (100 Mb)
<i>Drosophila melanogaster</i> ^c	3.5×10^{-9} (130 Mb)
<i>Arabidopsis thaliana</i> ^d	7.0×10^{-9} (120 Mb)
<i>Homo sapiens</i> ^e	11.8×10^{-9} (3200 Mb)

The Mutation Process: Cytological and Ontogenetic Considerations

In viruses, prokaryotes, and unicellular eukaryotes – with the notable exception of protists like *Paramecium* that have a macro- and a micronucleus – all mutations that are not strongly deleterious are heritable and become part of the polymorphism component of diversity. In metazoans most mutations arise in somatic cells and are therefore not heritable, although they may very well have an impact on the fitness of the individual carrying them. Mutations that arise in the cell lineages leading to propagules or gametes are however heritable. This applies in general to all multicellular organisms. In organisms with a germline (a terminal differentiation of specialized gamete-producing cells), differences in the timing of germline sequestration and in the number of cell divisions before gametogenesis can be studied carefully, and have been shown to have a major impact on the number of new mutations found in gametes. A good example is the observation that most of the evolution at the molecular level in different groups of animals (flies, fish, birds, and mammals) is “male driven.” In mammals, in X- and Y-linked homologous genes the male-to-female ratio of nucleotide substitution is close to 6 in humans and 2 in rodents, which corresponds closely to the ratio of male-to-female germline divisions by the time of sexual maturity. This means that in mammals, humans included, most mutations participating in molecular divergence arise in the male germline.

Factors Influencing the Fate of Mutations

Patterns of molecular diversity other than those created by a continuous flow of short-lived mutations, which remain unique to the individuals in which they arise, can be very striking. For instance, some of the loci encoding the antigen-presenting major histocompatibility complex (MHC) in humans show extremely high levels of amino acid and synonymous polymorphism as well as many alleles segregating at intermediate frequencies. However, loci in the human Y chromosome show little polymorphism and mainly low-frequency mutations.

In general, patterns of polymorphism are determined by mutation pressure, genetic drift, and natural selection. The effectiveness of the action of the last two forces depends on the effective population size and on the fitness effect of the mutation involved. In particular, genetic drift increases in strength with decreasing population size and this in turn hinders the deterministic action of selection.

The patterns of variation of selectively neutral mutations are almost completely determined by genetic drift, population size, and the rate of mutation to neutral variants. For selected mutations both drift and selection can affect the patterns. In the case of strongly deleterious mutations, the observed pattern is one of mutations unique to each individual and none segregating at high frequencies as such mutations remain in the population for only very few generations. When a steady state is reached between the number of new deleterious alleles being produced by mutation and those being removed by selection, one speaks of a mutation–selection balance. Strongly favorable mutations should not show any observable

polymorphism patterns for such mutations are normally fixed soon after being introduced in the population (if they are not immediately lost to drift) and practically do not participate in polymorphism. However, favorable mutations can be maintained at intermediate frequencies, for example, when the heterozygote has higher fitness. In this case one speaks of a balanced polymorphism (as in the MHC previously mentioned). For weakly selected mutations, genetic drift and selection are important, as we shall see below (*see* Nearly Neutral Theory). Note that the above considerations are mainly applicable to recombining populations because in asexual populations and in cases with very weak selection and low recombination intensity, situations can arise that require considering patterns and forces at the level of the whole genome or of long stretches of the genome.

Models of Molecular Evolution

The main models that make predictions about the patterns of polymorphism and divergence are the neutral theory proposed in the late 1960s by Motoo Kimura and the nearly neutral theory proposed in the early 1970s by Tomoko Ohta. Those two models emphasize the importance of genetic drift and mutation on molecular evolution. Predictions from those models have been compared to empirical patterns and to predicted patterns from complex models that involve the action of natural selection. All models agree that the vast majority of newly arisen mutations are deleterious, but they differ greatly in their assumptions about the relative proportions of neutral and beneficial mutations that participate in polymorphism and divergence.

Neutral Theory

Kimura's neutral theory (Kimura, 1983) postulates that both the fixation of genetic differences between populations and the patterning of genetic variation within populations are the results of random changes in the frequency of neutral alleles driven by genetic drift. This model assumes that most new mutations are either deleterious or neutral and that advantageous mutations arise quite infrequently and are quickly fixed or lost to drift so that they are not important for polymorphism. Most of the theory's predictions for polymorphism patterns assume mutation–drift equilibrium, i.e., that the rate of allele loss to drift is balanced by the production of new alleles by mutation. The predictions therefore apply only when the population size and the mutation rate have been constant for a long period of time.

The theory predicts that the amount of polymorphism within a population is proportional to the effective population size (N) and the neutral mutation rate (μ). Nucleotide polymorphism is normally expressed in terms of the parameter θ ($=4N\mu$), which can be interpreted as the average number of differences per nucleotide site between two alleles randomly chosen from the population. This divergence is the result of nucleotide mutations that have accumulated since the two alleles last shared a common ancestor. Theory has shown that the expected time back to this ancestor for an autosomal locus in a diploid is $2N$ generations, so that when each allele has been evolving independently for $2N$ generations, the expected

number of nucleotide differences between them is $2 \times 2N$ times the neutral mutation rate μ , i.e., $4N\mu$.

The neutral theory explains the fact that different genes and regions of the genome show different levels of polymorphism by assuming that the neutral mutation rate varies among such regions and genes because they are under different functional constraints. Alternatively, levels of polymorphism can also vary across genes because the effective population size can be reduced by selection against deleterious mutations at linked and unlinked sites ("background selection"). This effect can compel neutral polymorphism to change drastically across regions that differ in recombination intensity and deleterious mutation production.

Nearly Neutral Theory

Ohta's nearly neutral theory (Ohta, 1992), considered by many to be the "dominant paradigm for molecular evolution", was proposed in the early 1970s in order to account for two observations that could not be explained by the neutral model: the generation time effect for DNA divergence and the lower-than-expected levels of protein variation in natural populations. The model deviates from the neutral theory mainly because it assumes (1) that most observed molecular variation is slightly deleterious, (2) that mutation rates are correlated with the generation time (g), and (3) that the rate of molecular divergence for slightly deleterious alleles is inversely proportional to N . The nearly neutral theory is biologically realistic because it proposes plausible correlations of population genetic parameters like g and N with the origination and fate processes of molecular evolution, and because it avoids the unrealistic assumption of complete neutrality for most variation participating in polymorphism and divergence.

Under this model, slightly deleterious or weakly selected alleles, defined as those with selective coefficients close to the neutral boundary ($s \approx 1/N$), are considered major contributors to polymorphism and divergence in natural populations. Whereas the neutral theory proposes that the fate of neutral variants depends only on random drift, the slightly deleterious model builds on the fact that the fate of slightly deleterious variants depends on the joint action of both drift and selection. Which of these two processes is more important depends on the effective size of the population, because the efficacy of selection in removing slightly deleterious variants and fixing advantageous ones is higher in larger populations. In smaller populations, slightly deleterious mutations can increase in frequency and become fixed by genetic drift, but in large populations selection prevails and eliminates deleterious mutations quickly. The nearly neutral model predicts therefore that if most of the observed variation in natural populations is slightly deleterious, polymorphism patterns should be dominated by rare variants.

This model explains the lack of correlation between genetic variation and population size (especially in large populations) with the argument that when divergence and variation involve mainly slightly deleterious alleles, the amount of diversity in a population should be proportional to N but nevertheless reach a plateau when N is large enough for selection to impede slightly deleterious variants increasing in frequency. One main problem with this interpretation is that in organisms with very large population sizes one would not expect any

variation if most polymorphism is due to slightly deleterious variants (at least no amino acid polymorphism), which is clearly not the case.

Selection Models

Models where natural selection is the main evolutionary mechanism shaping patterns of polymorphism have originated from two contrasting philosophies. In one approach, selection is invoked to explain patterns of variability not consistent with neutrality (genetic hitchhiking and background selection models). That approach assumes that neutral explanations may still be appropriate null models of molecular evolution. In the other approach, complex selection models have been developed to explain patterns of polymorphism that fit (or do not) neutral expectations. That approach is centered on the premise that neutral models are incorrect explanations of the molecular evolutionary process (Gillespie's models).

Levels of neutral polymorphism can be reduced by the indirect effect of positive or negative selection on neighboring (linked) genomic regions. The extent of that effect is dependent on the level of recombination in the genomic region, on the strength of selection, and, in one of the models, on the mutation rate to deleterious alleles. In the "genetic hitchhiking" model, the fixation of a beneficial allele by directional selection (a selective "sweep") leads to reduction in linked neutral variation, as any neutral variants present in the chromosome where the beneficial allele first arises will also increase in frequency very rapidly as the beneficial allele rises in frequency toward fixation (thus "hitchhiking" with the selected allele). The width of the region affected by the selective sweep is predicted to be $\sim 0.1s/r$, that is, proportional to the selection coefficient (s) of the beneficial allele that is sweeping to fixation and inversely proportional to the recombination rate (r) per base pair (Gillespie, 2004). For instance, in genomic regions with average recombination rates in *Drosophila melanogaster*, a beneficial allele with a 1% advantage ($s=0.01$) could affect patterns of neutral variability in a region up to 100 kb around the selected site (Sella *et al.*, 2009). In the "background selection" model, selection against recurrent deleterious mutations reduces levels of neutral polymorphism at linked sites. The extent of this effect increases with the deleterious mutation rate and the strength of purifying selection, but decreases with the recombination rate. The strongest effects on reduction of variability are expected for deleterious mutations with intermediate selection coefficients, as strongly or weakly deleterious alleles will be eliminated too quickly or too slowly, respectively, to significantly reduce levels of linked neutral variation.

Selection models developed in the 1980s by John Gillespie seem to account for most of the empirical observations about molecular polymorphism and divergence (Gillespie, 1991). The models assume that balancing and episodic selection dominate the patterning of divergence and polymorphism at the molecular level. They predict that fluctuations of the environment can lead to the maintenance of polymorphism by balancing selection and, under the right circumstances (when the selective advantage of an allele is greater than the variance of the fitness effects of the alleles at that locus), to the fixation of favorable alleles. The models assume fitness effects that are

underdominant, overdominant, or that change in a random environment (Stochastic Additive Scale-Concave Fitness Function (SAS-CFF) model) or in a temporally fluctuating environment (Takahata, Iishi, Matsuda (TIM) model). The addition of environmental variability is biologically realistic since the existence of fluctuations in the fitness value of segregating alleles due to changes in the environment over ecological time scales is quite plausible. These models predict patterns of polymorphism similar to those predicted by the neutral models, which makes hypothesis testing very problematic.

Statistical Tests on Molecular Polymorphism

Of all the models of molecular evolution, only the neutral theory makes simple quantitative predictions about expected levels and patterning of genetic polymorphism. That fact makes the neutral model a very popular null hypothesis against which to test the importance of other evolutionary forces in shaping patterns of polymorphism. There are two basic families of statistical tests for neutrality: (1) models that test neutrality using polymorphism data from a single locus (below, this section) and (2) models that test neutrality using polymorphism and divergence data (*see* Combined Predictions for Divergence and Polymorphism).

The data required for the single locus tests are homologous DNA sequences collected from individuals of a single species. This family of tests compares three estimates of the neutral parameter θ , which equals $4N\mu$ for an autosomal locus in a diploid. The three estimates are or are straightforwardly calculated from (1) π , the average number of pairwise differences between the sampled alleles, which should be equal to θ , (2) S , the number of polymorphic sites in the sample, and (3) η , the number of mutations present in only one of the sampled alleles (singletons). Under neutrality the value of these estimates should be the same. The tests therefore ascertain whether departures from zero of the differences between any two of these estimates are statistically significant for the sample at hand.

Tajima, for instance, proposed to compare the values of π and θ_S (θ estimated by S) using his statistic D which is the difference between π and θ_S normalized by dividing the statistic by a factor proportional to the variance of the difference. Negative values of D are expected in the presence of purifying selection or following a purging of variation from the region by selection driving the quick fixation of a new mutation or a rapid increase in frequency of an allele previously present at a lower frequency (selective “sweep”). Positive values of D are expected with balancing selection and population subdivision.

Although the patterns predicted by the neutral theory are always used as null hypothesis, the patterns produced by the two main kinds of selection regimes (directional selection and overdominance) have also been described thoroughly, and their matching with the data has sometimes been striking. For instance, selective sweeps, the result of directional selection, tend to reduce neutral variation in regions linked to the selected site. This “hitchhiking” effect on neutral variation is more pronounced in zones with low recombination. Balancing selection increases the levels of variation over the neutral expectation in the sites adjacent to the balanced site by making the times to the

common ancestor at these linked sites more similar to that of the balanced site (i.e., to the time since the establishment of the polymorphism) than to the neutral time at unlinked sites. If the polymorphism is older than $2N$ generations, one should observe an increase in neutral variation in the region of the balanced site relative to the neutral expectation.

Empirical Observations on Levels of Polymorphism

Observations about patterns of variation can be very informative when asking questions about the nature and sometimes the magnitude of the evolutionary forces generating the patterns, such as: Why do some species have more variation than others? Is it due to differences in the rate of origination of mutations? Is it due to differences in the size of their populations? Is it due to recent evolutionary, demographic, and ecological events? Is it due to the species’ distributions over geographic space? Is it due to their breeding system? Is it due to the genomic context in which the mutations occur (e.g., the intensity of recombination and of deleterious mutation in and around the studied locus)?

The advent of methods for high-throughput genome sequencing has facilitated obtaining unbiased genome-wide estimates of nucleotide polymorphism for several species, although the most complete datasets still come from model species with fully assembled genomes like fruit flies and humans. Levels of nucleotide polymorphism vary widely across species (Table 2). Those differences are likely the result of differences in historical effective population sizes, which should influence levels of standing genetic variation as

Table 2 Levels of neutral nucleotide polymorphism in autosomal loci from different species of animals, plants, or bacteria

Organism	Nucleotide heterozygosity per silent site	Estimated effective population size (N_e) ^a
<i>Homo sapiens</i>	0.0011 ^b	9300 ^d
<i>Pan troglodytes</i>	0.0013 ^c	21,300 ^c
<i>Gorilla gorilla</i>	0.0016 ^c	25,200 ^c
<i>Mus musculus</i>	0.0079 ^d	580,000 ^d
<i>castaneus</i>		
<i>Drosophila</i>	0.0232 ^e	1,150,000 ^g
<i>melanogaster</i>		
<i>Escherichia coli</i>	0.0200 ^f	25,000,000 ^g

predicted by neutral models (i.e., at mutation–drift equilibrium nucleotide polymorphism should equal $4N\mu$). However, within a species the level of polymorphism can vary extensively across genomic regions, showing, in species where those comparisons can be conducted like *D. melanogaster*, a positive correlation between levels of variability at neutral sites and the rate of recombination (Figure 2). That correlation is consistent with patterns expected under the genetic hitchhiking and background selection models. Although both of those models can account for the low levels of polymorphism observed in regions of low recombination, only the hitchhiking model (especially with recurring selective sweeps) can account for the overrepresentation of low-frequency alleles in those regions.

An important conclusion from estimates of polymorphism is that the full haploid genomes of two randomly sampled individuals from any of the species studied to date should show a large number of nucleotide differences: $\sim 5 \times 10^5$ differences in *D. melanogaster* or $\sim 3 \times 10^6$ differences in humans. Thus, the level of standing genetic variation on which natural selection can act is substantial.

Diversity as Phylogenetic Divergence

How do genes, proteins, and genomes differentiate, and what limits how different they could become? Are there heterogeneities in the rates of divergence among different proteins, genes, and genomic regions? Do molecules from different organisms evolve at different rates? What are the mechanisms of nucleotide and amino acid substitution? Can we infer the genealogical relationships among different organisms from molecular data? Can we use molecular divergence data to date

evolutionary events? These are some of the questions addressed by researchers in the field of molecular evolution. This section will give examples and summarize the current answers to the first three questions, i.e., those most relevant to understanding the evolutionary dynamics of molecular diversity.

The Substitution Process

The fixation of new mutations gives rise to the divergence component of genetic diversity. This process describes how a new allele replaces the previously most common allele in the population, thereby becoming the common ancestor of all alleles at that locus. The dynamics of the substitution process are determined (1) by the rate of origination of new mutations in the population and (2) by the probability of fixation of such mutations. The main evolutionary forces affecting this process are mutation, genetic drift, and selection, with their relative importance differing for neutral, weakly selected, and strongly selected mutations.

Neutral autosomal mutants are produced in a diploid population at a rate of $2N\mu$ per generation, i.e., the number of new mutations produced in each generation is equal to the product of the number of gene copies in the population that can mutate ($2N$) times the mutation rate to neutral alleles per gene per generation μ . The same result applies for selected mutations if we let μ become the rate of mutation to strongly selected or weakly selected alleles.

The probability of fixation of a mutation depends on the selective advantage or disadvantage of the mutation, on the population size, and on the initial frequency of the mutation. For a newly arisen autosomal mutation the initial frequency is $1/2N$ in a diploid population, which for the neutral case

equals the probability of fixation of the mutation (since any of the $2N$ alleles present at any given moment can become the common ancestor of all alleles in the population some time later). For a nonrecessive mutation with selective coefficient s close to $1/N$, the probability of fixation is about $2s/(1 - e^{-4Ns})$. If the value of s is positive (advantageous mutant) and the population size is large such that $Ns \gg 1$, the fixation probability is twice the selective advantage of the mutant ($\approx 2s$). Even in this case, however, genetic drift is the main determinant of the fate of new mutations (e.g., 98% of mutations with 1% selective advantage are lost to drift). For a deleterious mutant (negative s) the fixation probability is lower than in the neutral case (but nonzero, stressing the importance of genetic drift) and is practically zero for strongly deleterious mutations.

The rate of substitution equals the average number of new mutant alleles entering the population each generation, times the probability that one of them will fix. For a neutral allele this equals $(1/2N) \times (2N\mu) = \mu$, i.e., the rate of substitution of neutral alleles equals the mutation rate (Kimura, 1983). For selected mutations the rate of substitution equals $4Ns\mu$, and is therefore dependent on the mutation rate of favorable selected mutations, the population size and the selection coefficient of the mutant. It is easy to see that for the neutral rate of substitution to remain constant across different populations it suffices that the neutral mutation rate does not change. For selected mutations, however, the substitution rate could vary much more since its constancy requires that three parameters do not change or that they vary in ways that balance changes in the others.

Models of Molecular Evolution

From their conception most theoretical models of molecular evolution dealt with both divergence and polymorphism using an explicit population genetic perspective.

Neutral Theory

Kimura showed that genetic divergence at neutral loci should increase over time due to the fixation of neutral mutations by random drift at a rate that equals the neutral mutation rate μ (see The Substitution Process) (Kimura, 1983). This predicted constancy in the rate of substitution matched empirical observations showing constant rates of amino acid substitutions per year for different proteins in a wide range of vertebrate lineages that had led E. Zuckerkandl and L. Pauling to propose the molecular clock hypothesis in the early 1960s. Although the match is often viewed as positive evidence for Kimura's neutral theory, some selection models can also produce clock-like divergence (see Selection Models). The observed differences in rates of evolution among different genes and the heterogeneity of divergence rates in different regions of a gene are explained by the theory as being the result of differences in the fraction of all mutants that are neutral for each given gene or region (i.e., different functional constraints).

Nearly Neutral Theory

Ohta's model assumes that most molecular diversity is slightly deleterious, and predicts that the rate of production and

fixation of neutral mutations is negatively correlated with organismal generation time (generation time effect), and that the rate of divergence for slightly deleterious changes is inversely proportional to the population size (Ohta, 1992). The negative correlation between generation time and mutation rate is expected when mutations occur mainly during DNA replication and the number of germinal cell replications per generation is the same across different organisms. The germinal cells of short-lived organisms should indeed experience more DNA replications per year than those of long-lived organisms so that more neutral mutations can be produced in short-lived organisms. Such an assumption corresponded well with observations from divergence studies from the early 1970s based on DNA hybridization that showed a strong generation time effect for noncoding DNA evolution. The generation time effect can be obscured in comparisons among distantly related organisms when they differ in developmental mode and germline ontogeny.

An important contradiction this theory tried to address was that protein evolution appears to be clock-like whereas noncoding DNA evolution shows a generation time effect. The neutral model explained the former by asserting that most amino acid replacements are neutral. The nearly neutral model asserted that protein divergence is mainly due to the fixation of slightly deleterious alleles, so it had to resort to postulating that generation time is inversely proportional to population size in order to account for the constancy of amino acid replacement rates. It was argued that small organisms have higher mutation rates per year due to their shorter generation times but that due to their larger population sizes, they fix slightly deleterious amino acid changes less readily. However, organisms with longer generation times have lower mutation rates but smaller population sizes so that they fix slightly deleterious mutations more easily. Therefore, the fact that across different taxonomic levels generation time correlates negatively with population size lets the rate of amino acid divergence appear clock like.

A major problem with this theory concerns divergence: slightly deleterious variants cannot accumulate indefinitely because they would decrease the fitness of the population thereby giving new favorable mutations a major role in the process. Additionally, in large populations, no divergence should occur because in them selection should be efficient enough to eliminate most slightly deleterious alleles.

Selection Models

Divergence data prompted Gillespie to propose his SAS-CFF and TIM selection models (see Diversity as Polymorphism: Selection Models) (Gillespie, 1991). He showed that there is excessive variation in amino acid divergence rates in different mammalian proteins using the index of dispersion $R(t)$, which is the ratio of the variance in substitution rate to the mean substitution rate. The index ranged between 2.5 and 7.5 although the neutral theory predicted it to be around 1.0 (as expected for a simple Poisson process). These high values of $R(t)$ led Gillespie to propose that the process of divergence is characterized by bursts of substitution during which alleles previously segregating at high frequencies become rapidly fixed by selection, followed by quiet periods with little substitution and long-lived intermediate frequency polymorphisms. This still allows for a molecular clock if the periods of bursting and

stasis succeed each other more or less regularly, leading to an “episodic molecular clock.” Nevertheless, neither these models nor the neutral and nearly neutral models can completely account for the excessive variance of the rate of amino acid replacement in mammals. Improvements of these models should include increasing the time frame over which the fitness effects of mutations change or fluctuate. However, the complexity of the models has already reached the point that they can fit almost any observation, which compromises their value for hypothesis testing. At this point one will have to assess the plausibility of their assumptions rather than the accuracy of their predictions.

Statistical Tests on Sequence Divergence

The comparison of the rate of substitution of nonsynonymous (replacement) and synonymous (silent) mutations (dN/dS) in homologous sequences from different species have been used to infer the occurrence of natural selection during protein evolution. In a protein-coding sequence that is evolving neutrally (and under no selective constraints) the rate of substitution at nonsynonymous or synonymous sites should be the same; thus, one expects $dN/dS = 1$. Alternatively, if purifying selection is removing a fraction of nonsynonymous mutations while not removing or removing a lower fraction of synonymous mutations then one expects $dN/dS < 1$. The vast majority of protein coding genes that have been studied show evidence of purifying selection ($dN/dS < 1$). This is expected because amino acid changes often disrupt the function of the protein whereas synonymous changes are less likely to have comparable consequences. Evidence of adaptive substitutions in a protein-coding gene are inferred when $dN/dS > 1$, that is, when the rate of amino acid substitution is greater than the rate of silent substitution. Although this approach is widely used to identify genes evolving under positive selection, it has relatively low power given that evolutionary rates are compared across the whole length of the gene. For that reason, statistical methods that allow inferring selection at particular sites of the protein or along particular lineages in a phylogeny have been developed.

Empirical Observations on Divergence Levels

One of the main patterns of divergence that have been described by protein and DNA sequencing studies is that rates of amino acid replacement in different kinds of proteins and in different organisms are extremely variable (Table 3). Histone H4, a protein involved in the packaging of DNA in chromosomes, is a striking case of an extremely conserved protein. Comparisons of H4 histones from plants and mammals show that only two amino acid replacements, over the 100 sites compared, have taken place since the two groups last shared a common ancestor about one billion years ago. However, viral envelope proteins, which are under constant challenge by the host immune system, change at extremely high rates – between a million- to ten-thousand-times faster than the fastest mammalian protein (γ -Interferon).

Table 3 also shows that rates of substitution at synonymous sites are higher than rates at nonsynonymous sites ($dN/dS < 1$).

Table 3 Rates of amino acid and silent substitution (in events per site per year)

Organism	Protein	Nonsynonymous rate	Synonymous rate
Human–Rodent	Histone 4	0.00×10^{-9}	3.94×10^{-9}
	Insulin	0.20×10^{-9}	3.03×10^{-9}
	Hemoglobin α chain	0.56×10^{-9}	4.38×10^{-9}
	Interleukin-1	1.50×10^{-9}	3.27×10^{-9}
	Ig kappa chain	2.03×10^{-9}	5.56×10^{-9}
	γ -Interferon	3.06×10^{-9}	5.50×10^{-9}
<i>Drosophila</i> ^a	<i>Adh</i>	0.90×10^{-9}	9.50×10^{-9}
	Esterase 6	3.03×10^{-9}	21.52×10^{-9}
Plants			
Grasses	<i>Adh1</i>	0.32×10^{-9}	7.00×10^{-9}
Grasses	<i>Adh2</i>	0.89×10^{-9}	5.99×10^{-9}
Palms	<i>AdhA</i>	0.41×10^{-9}	2.61×10^{-9}
DNA viruses			
Hepatitis B	P	1.45×10^{-5}	4.57×10^{-5}
RNA viruses			
Influenza A	Hemagglutinin	3.59×10^{-3}	13.10×10^{-3}
HIV-1	<i>gag</i>	1.70×10^{-3}	9.70×10^{-3}

However, in several proteins, amino acid replacements occur more frequently than synonymous substitutions ($dN/dS > 1$), for example, in the antigen recognition site of the Human Leukocyte Antigen (HLA) loci in humans, in fertilization proteins of abalone, in HIV proteins, in proteins involved in male reproduction (*Acp26Aa*), or associated with hybrid male sterility (*OdsH*) in *Drosophila*. In the latter locus, for instance, more amino acid changes have occurred in less than a million years than during the previous 700 million years. The rapid evolution of this gene is likely due to a change in function.

Scans for genes evolving under natural selection using the dN/dS approach have been conducted in species pairs for which annotated genome sequences are available. Humans have been a major focus of such scans given the interest in finding evidence of adaptation in genes that can provide any insights into what “make us human”. For instance, a comparison of 8079 homologous genes from humans and chimpanzee identified 733 genes with a dN/dS ratio greater than 1. Genes involved in immune response, olfaction, and spermatogenesis were among the most overrepresented genes showing evidence of adaptation.

Another major pattern evidenced by the data is that different taxa can evolve at quite different rates (lineage effects). For instance, a survey of substitution rates in 54 mammalian genes shows that rodents tend to have higher rates of synonymous divergence than primates, but their nonsynonymous rates are not significantly different. Similarly, sharks show a sevenfold reduction in rates of silent mitochondrial DNA evolution with respect to primates. Finally, endosymbiotic bacteria associated with aphids show higher rates of amino acid replacement than closely related free-living strains.

Combined Predictions for Divergence and Polymorphism

Two tests based on the mutual compatibility of divergence and polymorphism patterns have been developed and used with much success to test the neutral theory. When they reject neutrality, outside information can help in further identifying the forces that might have caused the rejection. The Hudson, Kreitman, and Aguadé (HKA) and the McDonald–Kreitman (MK) tests focus on the positive correlation between the amounts of polymorphism and the amounts of divergence expected under neutrality (given the linear dependence of both patterns on the mutation rate).

The HKA test compares the correlation between polymorphism and divergence at two or more loci. Its rationale is that if loci have different neutral mutation rates, their rates of divergence and levels of polymorphism should be equally affected. Selection is therefore inferred when the ratio of polymorphism to divergence varies too much over loci, a conclusion that requires sophisticated corrections to deal with the fact that, due to stochastic reasons, different loci can have different levels of polymorphism if they are not totally linked.

The (MK) test uses a similar contrast between polymorphism and divergence but concentrates on “loci” that are interspersed with each other over the sequence, thereby avoiding the need for the above corrections and drastically increasing the statistical power. This test is mostly applied to contrast synonymous (silent) and nonsynonymous (replacement) variation between species under the assumption that these two kinds of variation are homogeneously distributed along the coding region studied. The MK test compares the ratio of nonsynonymous to synonymous divergence (dN/dS) to the ratio of nonsynonymous to synonymous polymorphism (pN/pS). Under neutrality the two ratios should be the same, but adaptive protein evolution should make dN/dS greater than pN/pS . Furthermore, the difference between the dN/dS and pN/pS ratios is now typically used to estimate the fraction of amino acid substitutions (α) that have fixed by positive selection: $\alpha = 1 - [(pN/pS)/(dN/dS)]$.

Rejections of neutrality with the HKA or MK tests can be due to departures at the divergence or at the polymorphism level. For instance, an excess of amino acid polymorphism relative to amino acid divergence should be observed if variation is slightly deleterious. However, this “excess” could very well be due to a deficiency in silent polymorphism and/or an excess in silent divergence. If the ratio of amino acid replacement to silent substitution is significantly greater than the ratio of replacement to silent polymorphism, one could infer that natural selection has been driving the fixation of amino acid mutants beyond the neutral expectation, but again this could be due to a deficiency in amino acid polymorphism and/or in silent divergence. This is why outside information must be used to identify the causes of a rejection of neutrality by these tests.

Empirical Observations for Combined Divergence and Polymorphism Levels

Application of the MK tests to large-scale datasets has found evidence of adaptive amino acid substitutions in close to 50%

Table 4 Reported evidence of positive selection on large-scale datasets using the MK test

Group of organisms	Number of species	Evidence of positive selection (%)
Vertebrates	3	2 (67%)
Insects ^a	6	6 (100%)
Plants	13	4 (31%)
Fungi	2	0 (0%)
Bacteria	14	6 (43%)
All	38	18 (47%)

^aAll insect species are *Drosophila*.

Source: Reproduced from Fay JC (2011) Weighing the evidence for adaptation at the molecular level. *Trends in Genetics* 27: 343–349.

of the species surveyed (Table 4). Furthermore, in species where evidence of selection has been inferred, α , the fraction of amino acid substitutions that have fixed by positive selection, is quite high (often between 40% and 60%) (Figure 3). The range of estimated α values is quite similar (0–60%) regardless of what taxonomic comparison is considered (e.g., unicellular vs multicellular organisms, plants vs animals, and invertebrates vs vertebrates) and regardless of the inferred size of the populations being compared. In plants, only ~30% of the surveyed species show evidence of selection, but in every case the species with significant evidence of adaptive substitution are those with the largest effective population sizes. However, in bacteria, where every species is expected to have a very large population size, evidence of selection has only been observed in close to 40% of the species. Two of the most widely studied groups, *Drosophila* and humans, show contrasting patterns: although α is quite high (>30%) for all six species of *Drosophila* that have been surveyed, the evidence is equivocal in humans, where most studies show no evidence of adaptive substitution whereas few others suggest that α falls between 10% and 35% although the evidence is weak.

Outlook and Future Questions

Despite the suggestion that molecular adaptation is common in some organisms (e.g., more common in *Drosophila* than in plants or humans), the neutral and nearly neutral models may still remain useful for formulating null hypotheses. What is important is that more genome-wide polymorphism and divergence datasets are collected from a more diverse group of organisms. The use of next-generation sequencing methods will facilitate that task.

One important issue, however, that affects most models discussed here and that is yet to be satisfactorily confronted is the fact that most of the neutrality- and selection-based modeling of polymorphism and divergence is based on single-site theoretical approaches. In models with selection, single-site results, which assume that no further concomitant mutant is segregating, have been the standard, and the few efforts that have dealt with many concomitant mutations have assumed multiplicative fitness effects of mutations, i.e., that fitness is $(1 - s)^i$ when one carries i mutations. The latter assumption is made out of convenience and lack of clear alternatives but is not justified *a priori* nor has it been *a posteriori*. It is indeed not clear

Figure 3 Current estimates of the fraction of nonsynonymous substitutions driven by positive selection (α) across different taxonomic groups. Two subpopulations of *Saccharomyces paradoxus* are analyzed separately because they show strong evidence of genetic divergence and reproductive isolation. Reprinted from Fay JC (2011) Weighing the evidence for adaptation at the molecular level. *Trends in Genetics* 27: 343–349.

how selection acts on say synonymous or insertion/deletion variation and one cannot exclude that it acts at the level of the total individual genotype via a possibly complex epistatic relationship between the number of mutations and fitness. Similarly, it is very likely that the assumption that silent variation is weakly selected ($s \approx 1/N$) is incorrect as in fact too many species with too disparate values of N nevertheless manage to harbor intermediate levels of variation for synonymous changes, and to avoid fixing the major synonymous codon or having codon usages solely determined by mutation pressures. All of this could not be possible under the slightly deleterious model if N changes by more than a factor of 3 up or down from the value $1/s$. This point is also stressed by the fact that genes on the 4th chromosome of *Drosophila* show some clear signs of biased usage of synonymous codons despite the fact that the extremely low levels of polymorphism in this chromosome indicate that its local N should be reduced well beyond 10-fold, making the maintenance of such bias not possible. Exciting new patterns of polymorphism and divergence will have to be mined in order to address this and many other important questions, an endeavor

that will fundamentally bring the evolutionary and population genetic understanding of molecular diversity well beyond its present state.

The patterns of molecular diversity presented above have received attention because they facilitate the study and testing of hypotheses about evolutionary and population genetic dynamics. They are thus not necessarily representative of the phenomenon of molecular diversity in a more comprehensive organismal context. This explains, for instance, the absence of results on the evolutionary dynamics of molecular diversity with developmental consequences (albeit tentative efforts in this direction have been made during the last decade). Biologists, however, are well aware that this kind of diversity may be extremely important in evolution, but the present lack of knowledge about its behavior and nature makes it unsuitable for evolutionary and population genetic research that focuses on hypothesis testing. The narrow focus on variation suitable for hypothesis testing explains also this article's lack of an extensive presentation of some important molecular biological and biochemical constraints on molecular diversity

patterns. For instance, the dinucleotide motif TA is extraordinarily under-represented in all coding regions of *Drosophila*, yeast, and vertebrates (as is CG in vertebrate coding regions), and research on the forces underlying such motif preferences shows that they constrain molecular diversity in major ways and are rigidly conserved phylogenetically in some taxonomic groups (and thus under strong selection), but that they can also change markedly between groups or over time across chromosomes within groups.

Because these forces exert their effects on DNA without connection to gene homologies and chromosomal synteny maps, they are unapproachable using the methods presented above. It is an important upcoming task to widen our knowledge of such major and fundamental genome-architectural constraints and of how they affect molecular diversity and its dynamics in the natural-historical and organismic evolutionary sense.

The Value of Molecular Diversity and Conservation Biology

Diversity on earth is endangered and so is molecular diversity both at the polymorphism and divergence levels. Much has been written about the value of the divergence component of diversity (e.g., species richness), and also about the need to preserve the biological information contained in adaptations evolved over millions of years in species and locally adapted gene pools all over the world. Conservation biologists are aware that the polymorphism component of genetic diversity may be important for the survival of a species over evolutionary and even ecological time, and therefore they deem polymorphism worth preserving too. However, that they do it and the way in which they do it is important not only for evolutionary research but also for the other biological sciences. In fact the polymorphism patterns of many species with large effective population sizes have been shaped during millions of generations by the action of very small selection intensities. Such patterns may take too long to recreate by expanding a population and allowing selection to act for

sufficiently long enough time and/or they may be the result of selective effects too weak to study with standard laboratory techniques. The information in these patterns can indirectly guide researchers to subtle but important molecular biological, biochemical, cytological, and physiological effects of the selected mutations involved but will go lost if such populations disappear or their numbers are reduced drastically. For that reason, conservation biologists should also strive to protect large “unendangered” populations.

Glossary

Entropy An expression or measurement of the energy available for use by a system, including living systems; often described as the extent to which the system tends toward a state of disorder or randomness.

Extremophile An organism that requires, or grows optimally in, extreme environmental conditions; e.g., extremes of temperature, pressure, or acidity.

Heterotroph Literally, feeder on others; an organism dependent on organic material from an external source to provide carbon for growth.

Organism The smallest entity of life that can function as a whole, distinct from others of the same type; a single living being.

Photoautotroph An organism that uses inorganic material as a source of carbon for growth, and light as an energy source; e.g., plants.

The Nature of the Organism

The Basic Units of Life

Prior to modern evolutionary thinking in the nineteenth century, organisms were a primary focus of observation and explanation in biology. Darwin extended this tradition by reserving a central role for organisms and organismal diversity in his theory of evolution. He believed that evolutionary change resulted from the interaction of two factors, which he called “the nature of the organism” and the “nature of the conditions.” Of these two, Darwin (1872) proposed that the nature of the organism seems to be much more important; for nearly similar variations sometimes arise under, as far as we can judge, dissimilar conditions; and, on the other hand, dissimilar variations arise under conditions which appear to be nearly uniform, (p. 32).

Darwin thought that organisms were historically and developmentally cohesive wholes, and therefore it was in the nature of the organism to produce offspring that were all highly similar (but not identical) to each other and to their parents and other ancestors. He also postulated that reproduction produced variation without regard for environmental conditions and therefore it was in the nature of the organism to produce these offspring in numbers far exceeding the resources available for their support. This produced Darwin’s *Necessary Misfit* (Brooks and Hoberg, 2007; Brooks, 2010, 2011), an emergent property of which is natural selection. Reproductive overproduction produced variant offspring, many of which perished. Those that survived all had positive Darwinian fitness, but some were “fitter” (functionally superior) to others in the environment in which they were produced, and produced more descendants than their less fit relatives. Those merely adequate relatives, however, played a decisive role in distinguishing Darwinian selectionism from Lamarckian adaptationism. Whenever an environment changes, the most fit organisms in the old environment might not survive in the new, whereas some of the merely adequate in the old environment might have the adaptations necessary to

survive in the new one. Darwin’s perspective contrasted sharply with Lamarck’s proposal that adaptation was an immediate and directed response by organisms to their surroundings. Lamarck also believed that the nature of the organism was important in the production of diversity, but only because all organisms have the same ability to change according to their needs. Therefore, whereas Darwin postulated that the nature of the organism included autonomous, self-regulating properties, Lamarck believed that the nature of the organism was to be directly and completely connected to the environment.

The distinction between Lamarckian adaptationism and Darwinian selectionism became increasingly blurred in the second half of the twentieth century as biologists focused more attention on parts of organisms and less on organisms as wholes. Whatever the reasons for this reductionist movement, losing the perspective on whole organisms led to a loss of Darwin’s panoramic view of biological diversity. In the last quarter of the twentieth century there were many efforts to reemphasize the nature of the organism in evolutionary biology: treatises by Eldredge (1986), Brooks and Wiley (1988) and Maynard Smith and Szathmari (1995) are particularly attuned to Darwin’s original assertion about the nature of the organism and the nature of the conditions (Brooks, 2011).

Organisms as Energy Flow Systems

Lotka (1913, 1925) recognized that biological systems persist in space and time by transforming energy from one state to another in ways that generate and maintain organized structure. Maurer and Brooks (1991) proposed two classes of such energy transformations. Heat-generating transformations involve a net loss of energy from the system, usually in the form of heat. Conservative transformations involve changing free energy into stored states (e.g., structure). Because all conservative transformations in biological systems are coupled with heat-generating transformations, there is a heavy energetic cost to maintaining structure. Lotka (1913) suggested

that the interplay between flow and partitioning of energy in biological systems acts to slow the rate at which energy stored by conservative transformations is degraded by heat-generating transformations.

Nonequilibrium thermodynamics allows us to generalize this perspective. Living systems are nonequilibrium thermodynamic systems; they exchange matter and energy irreversibly with their surroundings and they maintain themselves in far from equilibrium conditions. The basic features of nonequilibrium systems can be summarized heuristically as

$$dS = d_e S + d_i S, \quad d_i S > 0$$

Total entropy changes (dS) can be subdivided into two components: $d_e S$, which measures exchanges between the system and its surroundings (changes in the surroundings), and $d_i S$, which measures production by irreversible processes internal to the system (changes within the system). This heuristic equation describes the “cost of living” for organisms because all organisms must take in high-grade energy and matter and dissipate lower-grade energy to their surroundings in order to survive. Energy degraded in the uptake of raw materials from the surroundings into the system is dissipated into the surroundings ($d_e S$). These exchanges are accompanied by a great deal of waste; hence, $d_e S$ is very large compared with $d_i S$. Nonetheless, it is in the manifestations of internal production that we perceive organismal diversity.

Internal production ($d_i S$) includes (i) dissipation from the system, called the external dissipation function (γ_α , or heat-generating transformations). Heat-generating processes occur when energy and entropy flow in opposite directions, with entropy production tending to move the system toward disordered states and (ii) dissipation within the system, called the bound dissipation function (γ_μ or conservative transformations). Conservative transformations are characterized by energy and entropy flowing in the same direction, with entropy production being retained within the system and tending to move the system towards more structured states. In biological systems, γ_μ can be further subdivided into allocations for accumulating biomass (γ_μ^b) and allocations for accumulating genealogical information (γ_μ^i). Heuristically (Brooks and Wiley, 1988),

$$d_i S = \gamma_\alpha + \gamma_\mu^b + \gamma_\mu^i$$

Organisms thus have a dualistic nature. As open thermodynamic systems, they must simultaneously interact with their surroundings and perform critical functions internally. They maintain themselves in a viable state by exchanging matter and energy irreversibly with their surroundings, taking in relatively high-grade energy and using it to perform useful work within themselves. This requires sensing of, and causal engagement with, the surroundings mediated by a physical distinction between the organism and its surroundings. That is, there must be an “inside” and an “outside” of the organism. For all organisms, cell membranes are simultaneously physical barriers between the inside and outside of the organism and highly selective mechanisms for modulating the exchange of matter and energy between the organism and its surroundings. For multicellular organisms, this barrier is a complex of cell membranes.

Organisms as Information Systems

Discovering the genetic code made it possible to begin thinking of organisms as information systems. Information systems consist of a source of signals, a channel through which the signals are transmitted, and a receiver and converter to translate the portion of the signals that made it through the channel into information. Early discussions considered the genetic system as the source, reproduction and ontogeny the channel, and the environment the receiver and converter. Genetic possibilities become phenotypic signals as a result of reproduction and ontogeny and become meaningful biological information as a result of causal interactions between the phenotype and the environment. The environment cannot be a receiver in a Darwinian world because it does not measure or interpret; its only causal interaction with biological information is elimination of some of it. If biological information is a material part of biological systems, however, it is possible for biological systems to be their own sources and receivers (Brooks and McLennan, 1990; Brooks, 2001, 2002, 2011). Although it is true that biological systems are localized in space, they are also localized in time. In other words, the receiver can be a “time.” The source is a genetic system at time t_0 , the channel is reproduction and ontogeny, and the receiver is the same genetic system at any given time $t_1, \dots, t_i$; thus, the receiver is temporally distinct from the source. If an information source precedes its receiver in time, it can produce the system that acts as receiver, and that system can then become a source. Information theorists use this perspective in designing self-correcting computer programs, which can enhance their own abilities to store and transmit information efficiently. The same holds true for biological systems: DNA has significant self-repair capabilities.

Biological systems are physical information systems, a type of nonequilibrium thermodynamic system, open to exchanges of matter and energy but maintaining a closed information system internally which functions to reproduce the system – to perpetuate lineages through time. They impose themselves and their functions on their surroundings and thus are self-stabilizing and self-organizing. They produce organized complexity cheaply ($d_i S$ is small compared to $d_e S$, and the portion of $d_i S$ allocated for the information system is small, in part because a small number of chemical templates are used to generate many organisms), variably (because even chemical templates are subject to the statistical mechanical vagaries of the second law of thermodynamics), and functionally (because organisms must exchange matter and energy with their surroundings in order to maintain themselves), but without regard for details of the surroundings (because the information system is embodied in relatively autonomous internal chemical production, $d_i S$, of the system). As the source and receiver of organized information, they can be the embodiment of the organizing principles for that information. Biological systems thus transmit information *through*, not *to*, their surroundings. This supports Darwin’s view that the nature of the organism creates the necessary conditions for selection processes.

Treating biological systems as physical information systems provides a causal basis for the origin of selection. Selection processes originate as a result of the necessity that biological

systems obtain matter and energy from their surroundings coupled with the relative autonomy of their information systems, which permits production of organisms regardless of the details of their surroundings. Without the constraints provided by this autonomy, there would be no selection; simultaneously, however, constraints provide systems with properties that limit the ways in which and the extent to which the system will respond to selection.

Putting it all Together

Biological systems, beginning with organisms, are functional wholes with respect to the way they engage their surroundings and with respect to their internal organization. A major component of internal organization is functional integration through the interdependence of parts, and this is most evident in the dynamics of ontogeny and in physiological processes. Evolutionary changes in biological systems do not occur all at the same time; thus, when such changes occur, only part of the system changes. All changes, whether point mutations on a chromosome or alteration of part of a complex mating ritual, must integrate with the rest of the system, which has not changed, in such a way that viable organisms result. The functional necessity of developmental integration creates stability domains within bioinformational phase space. Orderliness and organization in biological systems result from the interaction of selection processes with three aspects of the nature of the organism: (i) historical uniqueness, (ii) cohesive properties, and (iii) hierarchical organization (Brooks, 2001, 2002, 2011).

Historical uniqueness manifests itself in historical contingency and temporal irreversibility. Important organismal processes such as reproduction, development, aging, and death are inherently irreversible. Spontaneous irreversible behavior of this sort always involves growth and increasing complexity, and physical manifestations of at least some of the systems' history.

Cohesive properties range from membrane-bound nucleic acids to cell-cell adhesion and recognition, sexual reproduction and specific mate recognition systems, and common history of inheritance. Cohesion is especially important to evolutionary explanations; it is the "glue" of functional integration and hierarchical organization that are so characteristic of biological systems. Many biological processes that demonstrate irreversible behavior manifest such changes as a result of interactions among cohesive factors.

Hierarchical organization plays an important role in organismal diversity. Hierarchies provide stability, reinforce boundaries between organisms and their surroundings, allow increasing amounts of complexity without losing organizational coherence, and provide a way in which causation and control can be tied together. Eldredge (1985, 1986) emphasized two major forms of hierarchically organized biological structure. The ecological hierarchy is manifested by patterns of energy flow in ecosystems, and the genealogical hierarchy is manifested by patterns of ancestral relationships among organisms and species. Environmental and genealogical phenomena are good starting points for investigating hierarchical interactions because they are intimately connected in biology. Prebiotic environmental conditions established the

boundary conditions within which life could originate. Conversely, genealogical processes that characterize life are autonomous enough from environmental conditions to be capable of overrunning available resources and of changing the environmental conditions substantially. The longer life exists on this planet, the more it shapes the environment of the planet. Organisms are truly *Children of Time* (Brooks, 2010, 2011).

Diversity in the Real World: A Précis of Current Organismal Diversity

Organismal diversity is evolved diversity. No matter how distantly related two organisms are, they still share at least some features in common, such as cell membranes made of lipid bilayers and a common genetic code, linking them to a single phylogeny of life on this planet. Highlights of organismal diversity can thus be best recounted in a précis of organismal diversification – phylogeny. However, phylogeny is not a linear historical timeline. It is hierarchically branching and reticulating, producing organisms that are historically unique mosaics of ancient and recent traits, both functional and structural. Therefore, it is not possible to give even a précis of organismal diversity without twists and turns. The major transitions in evolution (Maynard Smith and Szathmari, 1995) provide excellent reference points. Maynard Smith and Szathmari suggested such transitions occur whenever life functions were compartmentalized and modularized in such a way that the reproductive flow of biological information was enhanced. They may enhance the survivorship of organisms in particular environments, thus increasing the likelihood that they will reproduce, or may enhance the mechanisms by which information is stored and transmitted, regardless of the particular environment in which it evolves. Maynard Smith and Szathmari highlighted what they considered to be the nine most important evolutionary transitions, all of which were examples of enhanced efficiency of information storage and transmission.

The oldest lineages of organisms on the planet are various prokaryotes, including bacteria and archaeans. These organisms are single celled, lack organelles or membrane-bound genomes, and exhibit only asexual or simple parasexual reproduction. Their cells form only rods, spheres, or spirals, and yet they have inhabited this planet continuously for almost 3 billion years and represent by far the largest number of differentiated lineages on the planet today, including the largest number of unnamed taxa. Representatives of the prokaryotes include chemoautotrophs (thought to have been the lifestyle adopted by the first living things), chemoheterotrophs, photoheterotrophs, and photoautotrophs. Photoautotrophic prokaryotes, primarily Cyanobacteria, were the first to demonstrate that organisms could change the environment of the planet, substantially affecting standing biodiversity. They did this by releasing large amounts of molecular oxygen into a reducing atmosphere, changing it in such a way that most prokaryotes became extinct or restricted to marginal habitats. This release of oxygen (the Great Oxidation Event), as well as associated nitrogen fixation, by prokaryotic photoautotrophs began about 2.4 billion years ago,

creating the conditions necessary for other life forms to evolve, so it is safe to say that prokaryote evolution played a major role in setting the stage within which all subsequent biological diversification occurred. Much later, an endosymbiotic association between a eukaryote and a cyanobacterium would lead to the evolution of the chloroplast (the modified cyanobacterium). Prokaryotes today include the so-called Archaea, sometimes called *extremophiles*, which may represent a collection of distantly related remnants of the diversity affected so much by the evolution of those photoautotrophs. Among the extremophiles are members of the halophilic *Halobacterium*, which grow best at pH 11.5, and the acidophilic *Sulfolobus*, growing best at pH 2 or 3 but able to survive at pH 0.9. There are methanogens, producing most of the planet's methane, including a host of symbionts living in the rumens of cattle and their relatives where they produce digestible carbohydrates for their hosts as well as methane. Another methanogen, *Methanopyrus*, which lives near ocean-bottom thermal vents, grows optimally at 98 °C but is able to survive at 110 °C and "dies of cold" at 84 °C. *Sulfolobus* is also a hyperthermophile, living optimally at 70–75 °C and dying at temperatures lower than 55 °C. *Thermus aquaticus*, isolated from hot springs in Yellowstone National Park, was the original source of high-temperature DNA polymerase, the enzyme used to catalyze the polymerase chain reaction (PCR) technology that has become indispensable to molecular biology. Most other prokaryotes are bacteria, which include some of mankind's most valued and most loathed organisms. Bacteria living in our digestive tracts are essential for proper nutrition, and *Escherichia coli* is the workhorse of molecular biology and biotechnology, including the pharmaceutical industry. On the other hand, diseases such as syphilis, anthrax, diphtheria, tuberculosis, smallpox, tetanus, cholera, and plague and a variety of agents of food poisoning, including *Salmonella* and botulism, are all caused by bacteria. These same disease-causing prokaryotes have also shown a tremendous degree of adaptability in the face of substantial human efforts to eradicate them. Strangely, there are no known pathogenic archaeans.

From within this great prokaryotic diversity evolved the first eukaryotes. Most eukaryote species, including the oldest surviving lineages, comprise single-celled organisms differing from prokaryotes by well-organized compartmentalization of functions within the cell. Cell energetics are handled by organelles called mitochondria and chloroplasts, which are thought to have originated as endosymbiotic prokaryotes (the mitochondrion being a modified α -proetobacterium symbiont). Digestion and excretion are handled by specialized vesicles within the cell that facilitate the movement of matter and energy in and out of the cell. Synthesis of amino acid building blocks for structural components takes place in specialized organelles called ribosomes. Finally, the storage, production, and transmission of information are compartmentalized inside a membrane-bound nucleus. Powered locomotion, first evolved by prokaryotes and often involving "appendages" (whip-like flagella, small, thin proteinaceous micro-filaments) to propel, swim, glide, twitch, and swarm through water or across surfaces, becomes highly effective in unicellular eukaryotes as a result of increasingly sophisticated cytoskeletal integration.

Most unicellular eukaryotes were once classified together in a nonmonophyletic collection of lineages called the Protista. We now know that "protists" are distributed across all of the major eukaryotic kingdoms, including the two kingdoms containing true multicellular organisms, the Unikonts (metazoans, fungi and related unicellular species such as amebas and choanozoans) and the Plantae (red algae, green algae, and land plants). Within this evolutionarily heterogeneous and diverse collection of lineages are the origins of the first sophisticated sexuality as well as alternation of sexual and asexual generations (numerous examples are found in ciliates, apicomplexans such as malaria, and various algae), the first sophisticated modifications of the cell membrane in ways that modulate organism–environment interactions (diatoms produce complex and beautifully sculpted exoskeletons), and the beginnings of true multicellularity, manifested by colonial aggregations of unicells that exhibit some degree of functional differentiation, such as the fruiting bodies of slime molds.

Single celled eukaryotes are major underpinnings of the heterotrophic portions of the biosphere. They are saprobes and detritivores, predators, and a variety of symbionts, ranging from commensal ciliates living in the tests of sea urchins and the rectums of frogs to mutualist flagellates living in termite guts, providing digestible carbohydrates for the insect hosts in exchange for their own food and a safe haven, and parasites of global socioeconomic significance, including the causal agents of amebic dysentery, malaria, giardiasis, African sleeping sickness, Leishmaniasis, and Chagas' disease. Most show enhanced reproductive output and complex life cycles, but *Giardia* and *Entamoeba* show some secondary losses of structures.

The photoautotrophic unicellular eukaryotes comprise four distinct lineages: dinoflagellates, red algae, diatoms, and green algae. The dinoflagellates, which owe their photosynthetic ability to an ancient endosymbiotic relationship with a red algae, are best known for causing *red tide*. Massive blooms of certain dinoflagellates produce large amounts of waste products that act as nerve toxins capable of killing large numbers of fish or of being concentrated in shellfish and killing those who eat them. The red algae include the well-known edible genera *Palmaria* (dulse) and *Porphyra* (nori). Green algae often form symbiotic relationships with other eukaryotes, including fungi, sponges, cnidarians, and various unicellular species. One species, *Oophila amblystomatis*, lives in the jelly surrounding spotted salamander embryos, where it thrives on the nitrogen waste from the developing salamander and produces oxygen in return. More astonishingly, this alga has been found growing inside the embryo's cells where it is surrounded by mitochondria. This implies that the salamander may be using the oxygen and carbohydrates produced by the photosynthesizing algae. Diatoms are ubiquitous phytoplankton that represent the primary source of photosynthesis (and oxygen production) in the ocean, although many are freshwater inhabitants. They are characterized by having bipartite siliceous shells (tests), exhibiting species-specific forms and beautiful surface sculpting. Because they are siliceous, these tests are highly resistant to decomposition. As a result, fossil deposits of diatoms are excellent indicators of past environmental conditions. Large deposits produce "diatomaceous earth," which has many industrial uses including

insulation, filtration, and metal polishing. Diatomaceous earth has also been proposed as a “nonpolluting” insecticide. Spreading diatomaceous earth on fields may clog the tracheae of pest insects but will also clog the tracheae of beneficial insects and may also affect the breathing structures of other animals, including those humans who apply it or work in fields on which it has been applied.

True multicellular lineages appear to have evolved at least four times, in the brown algae and plants, which are photoautotrophs, and the fungi and animals, which are heterotrophs. According to Maynard Smith and Szathmari, multicellularity represents an advance over unicellularity because in multicellular organisms the partitioning of functions can occur at the level of entire cells, tissues, organs, or organ systems rather than having to take place within each cell. Complex reproductive systems can evolve because multicellular organisms can produce gametes without having to become gametes. Given the large numbers of unicellular eukaryote lineages and the small number of multicellular eukaryote lineages, we conclude that it is difficult to achieve a multicellular state, despite the evolutionary payoffs. Perhaps this is because it is difficult to coordinate a population of cells. There are no true multicellular prokaryotes (bacteria form strings, strands, and mats of individual organisms), perhaps because prokaryotes show no functional partitioning at the cellular level. If so, true multicellularity could only have arisen after unicellular eukaryotes evolved. In a complementary vein, there are no known examples of secondary loss of the multicellular state.

The evolution of true multicellularity followed four different paths. Brown algae, up to 60 m long in the case of *Macrocystis*, can be found on ocean shores with pounding surf, in relatively quiet near-shore meadows, or floating in the open ocean. The Sargasso Sea, for example, is an enormous mass of floating *Sargassum*. Although relatively species poor, brown algae can be abundant. They exhibit differentiated tissues and even organs, including holdfasts and filaments, which are analogs of roots and leaves that provide homes to a diverse array of animal life. Some have gas-filled bladders which may contain up to 5% carbon monoxide – enough to kill a human. Cellular cohesion in brown algae is provided by alginic acid in the cell walls. This is a gummy polymer of sugar acids that cements cells and filaments together and provides the glue for the holdfasts. Alginic acid is an important commercial emulsifier in ice cream, cosmetics, and other products. Larger pieces of brown algae, especially some kelp species, are considered delicious and healthy food sources for humans.

The second group of multicellular photoautotrophs are the plants, sister group of the Chlorophyta; a group containing most, but not all, of the green algae, in which aggregates of single-celled organisms showing some degree of functional differentiation has evolved more than once (e.g., *Volvox* and *Micrasterias* (sea lettuce)). Unlike the brown algae, which originated in the sea and have remained there, plants are the descendants of an aquatic lineage that invaded and diversified on land. Cellular cohesion in true plants is provided by plasmodesmata, cytoplasmic strands connecting adjacent cells. Many plants exhibit a high degree of adaptability or permissiveness with respect to genome-level evolutionary modifications. Polyploidization is common among many

groups, including both autopolyploidization and allopolyploidization as a result of interspecific hybridization.

The land represented an excellent habitat for photoautotrophs because air transmits more sunlight than does water, in which light of sufficient quality for photosynthesis does not penetrate deeper than approximately 50 m. However, being on land also posed problems, one of which was structural: air provides little support compared to water. In the absence of inherent structural support, plants could only sprawl on the land – they could never rise above it. Cell walls made rigid by the carbohydrate cellulose provided the necessary structural support. Subsequent evolution of vascular tissue in a moss-like ancestor, then a sophisticated tubular transport system (tracheids) in the ancestor of the sister group of the mosses (those plants called, not surprisingly, Tracheophytes) enabled water and nutrients to be transported against gravity to considerable heights. Rigid cell walls and the tracheid system provided opportunities for tremendous vertical growth, represented by the convergent evolution of tree forms in many groups (including giants up to 110 m tall) and a tremendous flow rate of water and nutrients. A single maple tree only 15 m tall may support more than 175,000 leaves with a total surface area of more than 675 m², transporting up to 220 l of water per hour from the soil throughout the tree and eventually into the atmosphere through evaporation from the leaves.

Terrestrial life that is truly independent of aquatic environments must be associated with suitable reproductive modes. When ancestral plants moved onto land, they brought with them the large stationary eggs characteristic of their closest relatives. In all land plants, when these eggs are fertilized, the resulting embryos are sporophytes contained within a protective covering produced by the parent. Those ancestral plants also brought with them flagellated sperm, maintaining a dependency on aqueous surroundings for reproduction. This limited plants to living in moist environments, places in which thin layers of water or water droplets allowed sperm to swim to the egg. Only when nonaquatic male gametes (pollen) evolved in early angiosperms did plants become completely terrestrial. The evolution of pollen, however, created a new problem; since the sperm are no longer motile, the plant depended on other means of transportation, such as wind or pollinators like birds and insects, to achieve fertilization.

Once firmly established on land, major events in plant diversification were associated with increasing compartmentalization and modularization of the organism, all integrated and coordinated chemically and without a centralized nervous system. They elaborated functionally differentiated nonreproductive body parts, especially roots and leaves, that became specialized habitat for other terrestrial dwellers, creating novel opportunities for diversification of those species and coevolutionary feedback that affected their own evolution as well. Their root systems helped plants modify the soil in ways that enhanced the lives of the plants themselves but also affected the lives of other types of organisms living in the soil. Some legumes (e.g., clover, soybeans, alfalfa, and peanuts) have a symbiotic relationship with bacteria living in root nodules. The bacteria convert atmospheric nitrogen to ammonia, a more useable form of nitrogen. This process helps fertilize the soil and is the reason why many farmers rotate

crops, planting clover or buckwheat every so often to rejuvenate fields naturally. Some plants, on the other hand (e.g., black walnut), produce toxins in their roots that diffuse in the soil, inhibiting the growth of other plants. Still others, including common plants such as marigolds, secrete substances from their roots that deter plant-consuming soil nematodes and thus can be planted as a nontoxic nematicide border in gardens.

Aboveground vertical growth in tracheophytes led to a proliferation of habits – plants, shrubs, bushes, vines, and trees. This vertical structuring allowed complex communities to form, within which the various plants created their own ecological interactions by shading each other. Plants differ in the relative amount of biomass allocated to below- and aboveground structure. This led to complex ecological interactions among root systems. In the tropics, for example, most plant biomass is aboveground. Tropical ecosystems have nutrient-poor soils, so most of the productivity is tied up in the aboveground biomass, which is why deforestation can be so devastating to the ecosystem. In temperate areas in which there is more humus in the soil, a much larger proportion of plant biomass is belowground. In fact, a given plant may participate simultaneously in one set of aboveground and another set of belowground ecological interactions, just with other plants, depending on what species the plant belongs to and where it happens to be growing.

Plant organismal diversity is also associated with major modifications of the reproductive system, each of which has many variations. Primary among these was the evolution of seeds, which are embryos protected by a covering of nutrient tissue provided by the parent. These multicellular protective coats, containing cellular contributions from as many as three generations, are a source of protection and nutrition for the embryos that may allow them to withstand substantial periods of environmental harshness and still be capable of germinating. The earliest seed plants produced seeds exposed directly to the environment, called gymnosperms (naked seeds: e.g., conifers). Angiosperms (hidden seeds: e.g., flowering plants) evolved when the ovaries, containing the seeds, expanded into fruits, hiding the seeds and providing more protection. The evolution of double fertilization at more or less the same point in time, producing triploid endosperm, provided even more nutrition for the embryo. In essence one grain of pollen fertilizes an egg, while another grain fuses with two maternal nuclei, forming a nutritive tissue that is genetically distinct from the developing embryo. Coconut milk, coconut meat, corn, and wheat flour are examples of extensive endosperm.

Angiosperm diversification produced some amazing organisms. Some plants, like Venus Flytraps and Sundews, are predators. The pitcher plant, *Nepenthes rajah*, produces large urn shaped structures that can hold up to 2.5 l of digestive fluids. Small animals, mainly insects but occasionally frogs, lizards, birds, and even mammals, which fall into the fluid cannot escape, drown and are eventually digested, providing nutrition to the plant. The pitcher, in turn, is home to numerous species, including many predatory arthropods that may feed on the trapped organisms, and various mosquito larvae that may not be able to develop anywhere else. Other plants are parasitic. Indian pipe, which has lost its chlorophyll, is parasitic on fungi, which are themselves associated

with tree roots. The fungi exchanges minerals for carbohydrates with the tree, and the Indian Pipe taps into that exchange, in effect “stealing” nutrition and giving nothing back. Dodder seedlings grow preferentially toward volatile chemicals released by suitable host plants. Once contact is made, the dodder sends projections into the vascular system of the host, loses its roots and become completely parasitic. The seeds of some plants need to be burned by forest fires in order to germinate, others must pass through the intestinal tracts of herbivorous vertebrates to germinate and/or be dispersed. Perhaps the most famous example of this latter interaction is “civet coffee,” the most expensive type of coffee in the world. A civet eats coffee fruits, digests the sweet pulpy, outer layers then passes the seeds, which have been slightly modified by the digestive process, when it defecates to mark its territory. The final, and perhaps most recognizable, major innovation in land plants was the evolution of flowers, which are specialized and self-contained reproductive modules. Flowers represented an enormous potential for reproductive cohesion and diversification.

The evolution of plants was followed closely by the evolution of herbivores, especially among the nematodes and insects. This in turn was followed by the evolution of a variety of antiherbivore adaptations. Defenses against herbivory include both diminution and elaboration of the part of the plant being eaten, the evolution of deterrents such as thorns, and storage of toxic metabolic by-products in tissues that are the targets of herbivory such as leaves and stems. Likewise, the diversification of flowering parts is also associated strongly with the diversification of particular groups of animal pollinators, again most notably insects, although nectivorous birds (e.g., hummingbirds) and mammals (e.g., bats) also play a role.

Plants exist in many seemingly inhospitable habitats, particularly desert and boreal regions, where the evolution of resistant seeds as well as specialized reproductive, root, and stem and leaf systems allow them to survive and thrive. Cacti and other succulents represent convergent evolution of water-retaining and evaporation-resistant body forms that can survive in desert conditions. Many plants are able to flourish in nearly marine salinity conditions, although none is truly marine. Mangroves, for example, are able to excrete excess salt from the water they absorb in the tropical coastal estuaries in which they live. Plants also thrive in seasonally fluctuating environments. This is helped by the evolution of resistant seeds but is also enhanced by the ability to synchronize growth and reproduction with permissive times of the year. For example, the ability to shed leaves deciduously apparently arose as an adaptive response to seasonally dry climates but today functions in seasonally cold climates as well.

Tapping an almost unlimited energy source (sunlight), coupled with their sophisticated means of compartmentalization, has made plants extremely important to humans and to the biosphere. Terrestrial plants improve air quality by fixing carbon and producing oxygen and improve soil quality by fixing nitrogen. Plants that have adopted life in freshwater habitats are often quite sensitive to changes in water quality and are thus useful as indicators of pollution. Those having extensive aquatic root systems may also be excellent biofiltration systems; water hyacinths, for example, can actually

improve water quality. The cultivation of plants was a major event in human evolution, which ironically provided the conditions for the growth of human population and technology that now threaten our existence by threatening the biosphere. Different plants allocate substantial amounts of nutrients into root systems, especially tuberous ones, into stems and leaves, and into reproductive structures such as nuts, seeds, and fruits. Virtually any part of a plant may be highly edible for humans or their domestic animals. Simultaneously, substances functioning to deter herbivory or competition from other plants may also serve as sources of useful materials for humans, ranging from spices to pharmaceuticals. The American yew tree sequesters a compound called taxol, which has significant effects on certain forms of cancer; a close relative, the European yew, produces a similar compound called taxotene, which also has anticancer properties.

Fungi represent one of the two major groups of multicellular heterotrophs. Among living groups, fungi are apparently the sister group of choanoflagellates and animals. Cellular cohesion in fungi is provided mostly by default: The vegetative body of a fungus, called a mycelium, comprises many hyphae, which are filamentous multicellular extrusions maintaining cohesion among the cells by forming only incomplete cellular divisions, or septa, between them.

To many people, the presence of fungi indicates that something has gone wrong – one's basement is too damp or one's bread is too old. To others, fungi are something quite different: they are the major recyclers and decomposers of the biosphere, found most commonly in association with the refuse of the biosphere, including that of our own civilization. This is because most fungi are very adaptable saprobes, highly tolerant of great ranges in temperature and osmotic, especially hyperosmotic, conditions. A considerable number of fungi are parasitic and a few are even predators, attacking small animals such as soil nematodes. Fungi are very flexible reproductively, reproducing asexually or sexually with mating types not distinguishable as male or female and exhibiting an enormous diversity of variations on the general eukaryote theme of alternation of generations. They are the primary source of cellulose and lignin breakdown in the environment. All of these features make them excellent agents for bio-remediation. They can become established in highly degraded habitats and actually improve them, creating conditions that can support yet more life. Tropical forest soils, for example, lack much humus but have enormous mats of fungal hyphae forming mycorrhizal mutualisms on and in plant root systems, which maintain vital nutrients and structural cohesion in the small amount of soil that is present. Fossil evidence suggests that mycorrhizal associations are at least 300 million years old.

Of the numerous fungi phyla, only three are well known to most people. The Chytridiomycota, or water molds, may be the sister group of the rest of the fungi. They have recently made the news because they are implicated in massive die-offs of amphibians living above 1000 m elevation throughout the world. Many chytrids are known to be parasitic, with some exhibiting complex life cycles involving two different hosts. A few have been found that are predators of nematodes. Members of *Arthrobotrys*, *Dactylaria*, and *Dactyella* produce three-celled loops that entrap nematodes as they wend their way through the soil; once trapped, the nematode cuticle is

invaded by hyphae and ingested. The Ascomycota or sac fungi contain some of the most valuable and dangerous species to human health and cultural development. The mold that tells you your bread is too old is likely *Penicillium*, the original source of the world's first broad-spectrum antibiotic, penicillin. Two other members of the genus, *Penicillium camembertii* and *Penicillium roqueforti*, are required to produce fine cheeses. Some members of *Aspergillus* are essential to the production of soy sauce and sake, whereas others can cover edible products such as peanuts with carcinogenic aflatoxins. *Saccharomyces cerevisiae* (Baker's yeast) is used to make bread, wine and beer, while morels and truffles are some of the most expensive fungi on the culinary circuit. *Pneumocystis jiroveci*, which lives in most people's lungs, causes severe pneumonia in people with compromised immune systems (e.g., HIV/AIDS or cancer patients). The sister group to the sac fungi, the Basidiomycota or club fungi, includes most of the edible fungi, the mushrooms and chanterelles, as well as fungi that are sources of legal (ergotamine) and illegal pharmaceuticals (e.g., psilocybins such as magic mushrooms) and some of history's most deadly toxins (e.g., Death cap, Destroying Angel, Deadly Webcaps). This group also includes rusts and smuts, which can cause serious diseases in agricultural plants. Many club fungi produce microscopic spores that are forcibly ejected into the air (they are called ballistospores). Being light allows the spores to be transported on the slightest of air currents, but being small means that friction (drag) will quickly slow them down, dramatically decreasing their dispersal potential. At least one species (*Sclerotinia sclerotiorum*) has solved the drag problem by releasing puff after puff of spores in a synchronized wave. The ballistic release creates its own airflow, moving the spores outwards, and even allowing them to stream around obstacles. This cooperative venture among spores carries them up to 20 times farther than a single spore ejected on its own.

On their own, fungi are ubiquitous and numerous throughout the world. In addition, some fungi form mutualistic associations with green algae or cyanobacteria. These associations, called lichens, are perhaps the champion extremophiles of the multicellular world. Extremes of heat and cold and dry and wet do not seem to deter lichens, who often flaunt their hardness by living on rocks, slowly but inexorably breaking them down into dust. They can survive long periods of desiccation, and were even shown to return unharmed after 10 days of exposure to the harsh radiation, temperatures, and vacuum in outer space.

The second group of multicellular heterotrophic eukaryotes are the Metazoa, or true animals. Animals maintain cellular cohesion by means of extracellular matrices of cell-adhesion proteins. Regulated cell growth, programmed cell death, cell-cell/cell-matrix adhesion, developmental signaling, recognition of self and cell type specialization, originated in the common ancestor of the metazoans. These major novelties were driven, in part, by rampant gene duplications; nearly 75% of animal-specific gene families arose by duplication in the metazoan ancestor greater than 600 myra. Unlike plants, which invaded the land early and diversified there, most animal diversification occurred in the ocean, and various groups have invaded freshwater and terrestrial habitats convergently. Even today, most metazoan organismal diversity is

in the sea. A great deal is known about metazoans, probably because many of them are large enough to be seen with the naked eye and active enough to engage visually oriented organisms such as ourselves. Most metazoans, including their sister group the Choanoflagellates, however, are microscopic. Highly complex and sophisticated adult organisms, such as some rotifers, may be as small as 50 μm .

The array of metazoan body plans provides clear evidence of modularization and compartmentalization. Metazoan bodies range from aggregates of specialized cells in sponges and placozoans to defined body forms composed of specialized tissues in cnidarians and ctenophores, with organ-level organization beginning with platyhelminths, and complex organ systems in the majority of the other metazoans. Body cavities emerged very early in metazoan evolution as effective ways of physically compartmentalizing organ-level modules and laid the evolutionary groundwork for specialized compartments within body cavities, called segments, metameres, and tagmata. Metazoan bodies may be asymmetrical as in sponges, radially symmetrical as in cnidarians, bilaterally symmetrical as in the majority of metazoans, or even biradially symmetrical as in ctenophores and echinoderms. Developmental patterns among metazoans tend to be highly conserved within major groups, although secondary loss of structures is not uncommon; the platyhelminthes appear to be descended from an ancestor that lost its body cavity, and a large group of parasitic platyhelminths, dominated by the true tapeworms, has secondarily lost its digestive tract as well.

Many metazoans are conspicuous because they tend to move around a lot. Modes of locomotion are diverse, but most are variations on swimming, creeping, or crawling. Sophisticated locomotion in metazoans is highly correlated with enhanced cephalization and neural integration. Cephalopod mollusks have water-jet propulsion provided by specialized siphons. Complex appendages for swimming, walking, and running, evolved in the arthropods and the chordates. Indeed a few chordates like snakes and some lizards are capable of sophisticated movements without limbs. It is within these two groups that organisms capable of true powered flight emerged.

All metazoans are heterotrophs, but they exhibit the entire range of heterotrophic functions – they are saprobes, detritivores, filter and suspension feeders, predators, herbivores, commensals, mutualists, parasitoids, and parasites. Herbivory is uncommon among marine metazoans but is a major attribute of the structure of terrestrial ecosystems. Modern herbivore diversity is concentrated in the insects, the amniote vertebrates, and the nematodes. Interestingly, no metazoans ever evolved the ability to digest cellulose so many of them dine on plant cells and tissues that contain nutrients in a form other than cellulose. Animals that actually gain nutritional benefit from cellulose are hosts to a variety of prokaryotic and eukaryotic microbes capable of breaking cellulose down into less complex carbohydrates, which can be absorbed by their host. Although this form of herbivory seems to be very successful when it evolves, it does not appear to have evolved often, presumably because it is difficult to acquire the proper symbiotic microbes, provide a suitable home for them in the intestine, and provide a means of transmitting them to offspring. For example, hatchling iguanas must consume fecal

matter from adults in order to acquire the necessary microfauna to digest cellulose.

Parasitism has evolved in virtually every group of metazoans. The phylum Acanthocephala is entirely parasitic, as are the vast majority of platyhelminths, including the well-known digeneans (trematodes or flukes) and eucestodes (tapeworms), and many nematodes and arthropods. There are very few parasitic species of chordates, the most famous being lampreys that attach themselves to fishes, rasp through their skin, and feed on the blood and fluids oozing out of the wound. In some deepsea anglerfishes, a male begins life as a very small, free living creature that spends his time trying to locate the much larger female. Once he finds her, he attaches, digests her skin until he fuses with her bloodstream, at which point he begins to atrophy, losing gut, brain, eyes, etc. until he is nothing but a bag of sperm, nourished, and transported by his mate.

Reproductive modes are diversified in metazoans. Most metazoan organisms are either males or females, although hermaphroditism is not uncommon in members of some of the oldest lineages. Gonads may be transient specialized cells or tissues or permanent organs and organ systems. Reflecting their ancient origins and diversification in the ocean, fertilization is plesiomorphically external in most groups. Internal fertilization, in which the female provides the aqueous medium within which the sperm can swim to the ova, has evolved multiple times. The ancient eukaryotic theme of alternation of generations is carried forward into metazoan evolution, although it drops out in several lineages convergently. In many cases, the asexual and sexual portions of the life cycle are ecologically partitioned; in most cnidarians these stages are characterized by distinct medusa and polyp forms with distinct ecologies. However, even for metazoans that do not exhibit alternation of generations, it is common for the larvae and adults to have very different life-styles. Most larval frogs, for example, are herbivores, whereas virtually all adults are insectivores. Among ecdysozoans (nematodes, rotifers, tardigrades, kynorhynchs, gastro-trichs, acanthocephalans, and arthropods), haplodiploidy is a common theme, setting the stage for extreme sexual size dimorphisms and asymmetrical sex ratios biased heavily toward females. Many metazoans are parthenogenetic, forming unisexual female lineages. In some cases, these lineages are entirely self-sustaining. For example, in some gynogenetic lizards, females court one another, with one partner displaying typical “male” behaviors, and the other typical “female” behaviors, and vice versa. This mutual courtship stimulates ovulation. In others, such as the gynogenetic poeciliid fish called the Amazon molly, sperm from males of a parental species are required to trigger embryogenesis, even though no genetic information from the sperm is incorporated into the embryo. A few metazoans, primarily tropical reef fishes, begin life as one sex, then change to the other sex depending on the social conditions around them. The production of two different sexes itself is not a simple process. Sexual differentiation is controlled by genes on sex chromosomes in many metazoans, although the particular chromosomes are not the same in all groups. In other animals, most turtles, crocodylians and many lizards, there are no sex chromosomes; offspring gender is determined by incubation temperature. Small changes in

temperature (e.g., through global climate change) can have a dramatic effect on sex ratio in these animals, even eliminating one gender altogether.

Another major theme of metazoan organismal diversity is temporal synchronization of reproductive cycles. Perhaps the most extreme case is that of the tropical Pacific polychaete called the Palolo worm, in which the entire species reproduces in a single night each year. Frogs living in deserts escape desiccation and heat by aestivating in burrows most of the year. They are awoken by the sound of rain and emerge en masse to breed during the brief, torrential rains. A more familiar example is that of anadromous salmonid fishes, in which adults return to their natal streams after spending 3–5 years in the ocean, reproduce, and die. Once they begin the movement into freshwater, salmon stop feeding and begin breaking down their own tissues for energy, all of which is used for getting to the spawning grounds and reproducing. In herbivorous insects reproductive synchronization is tied to cycles of growth and reproduction in the different plants they eat.

One of the most arresting features of animals is complex behavior, especially with respect to reproduction. This can be manifested in sophisticated interactions among males, among females, between males and females, in parental care, or even in complex combinations of all possibilities. Complex mating rituals have been documented in tardigrades, in which males are known to apply ritualized strokes to females to encourage them to reproduce. Mollusks (especially cephalopods), arthropods (especially insects), and chordates (especially vertebrates) are the best examples of sophisticated behaviors among metazoans. All three groups have evolved complex control and sensory integration involving neurochemical systems and strong cephalization.

Parental care is not restricted to mammals, nor is it primarily the domain of females. Some leeches are known to carry their offspring on their abdomens for a period of time after birth. In many species of fish, the male alone cares for the eggs and fry. Amphibians, particularly frogs, have evolved more ways to care for offspring than any other group. Some species carry their eggs and tadpoles on their backs, others swallow the fertilized eggs and the tadpoles develop in either the mother's stomach or the father's vocal sac (depending on species) and climb out through their parent's mouth when they have metamorphosed into froglets. Most caecilians, relatives of frogs, are viviparous. In some species the mother secretes a rich assortment of lipids and proteins into the top layer of her skin, which her offspring then peel off and eat using specialized teeth.

One outcome of integrated and sophisticated behaviors is sociality. Maynard Smith and Szathmari (1995) designated the evolution of social systems as one of the nine major transitions in biological evolution. Social systems permit functional compartmentalization at the level of different organisms within a social group. This level of modularization and compartmentalization is best seen in the social insects, notably bees, ants, and termites, whose colonies function very much like super-organisms. In bees and their relatives, colonies consist of many sexually inactivated females (workers) and a smaller number of reproductively active males called drones, whose only function is to mate with the only reproductively active female, the queen. Ants, also social

hymenopterans, differ from bees and their relatives by having males that die shortly after reproducing with a queen and by exhibiting a tremendous range of morphologically distinct, functionally stereotyped workers and soldiers. Ant societies fascinated Darwin, especially their propensities to wage war, make slaves, use tools, construct complex domiciles, and engage in agriculture, farming fungi and milking aphids for nutrients. Termites are the third major group of social insects. Their colonies comprise a single queen and king who do all the reproducing. Sexual inactivation of offspring is maintained from one generation to another by pheromones spread through trophallaxis, which is the mutual feeding of nymphs. Workers and soldiers produce pheromonal secretions whose proportions in the colony act to maintain suitable proportions of each type of individual in succeeding generations. One of the strangest examples of social caste systems has just been recorded in digeneans, parasitic flatworms with a complicated life-cycle that includes the repeated clonal production of infective larvae inside a snail. There are two types of infective larvae: large, slow moving, reproductively active primary morphs and small (about 64 times smaller), thin, very active secondary morphs. The secondary morphs do not reproduce. Instead, they are specialized for recognizing and attacking larvae from different flatworm species. These "soldiers" cluster in areas of the snail that are the most likely to be penetrated by other larvae. When an invader is detected, the soldier attacks, grasping the invader with its large muscular pharynx, either swallowing it whole, or lacerating it and sucking it dry.

Some vertebrates, including many primates, also form social systems. These tend to be much less stereotyped than those of the insects, with more flexibility in roles in which individuals perform multiple tasks and all are reproductively competent. Members of vertebrate societies never lose their individuality. Actual reproductive patterns are constrained by behavioral dominance hierarchies, both male and female, that can be quite complex and can be based in large part on kinship. None, other than humans, come close to the frenetic and compartmentalized social activity seen in the colonies of social insects.

The predominant metazoan groups are the chordates, nematodes, arthropods, mollusks, annelids, and echinoderms. The most organismally diverse group is the Ecdysozoa, which includes the nematodes and the arthropods. Within the arthropods, the insects alone represent more than 1 million named species, with many more remaining undescribed. Nematodes may be as species rich as insects, but only 15,000 nematode species have been named. Feats of relative strength and tolerance of extreme environmental conditions are legendary among the insects; among the ecdysozoa, however, tardigrades may be the most amazing extremophiles of all, being capable of entering a state of cryptobiosis. Under desiccating conditions, tardigrades can experience a loss of total water content from 85% of their body weight to 3%. Furthermore, while in this state, tardigrades can withstand, sometimes for years, extreme temperatures, including cold to near absolute zero, ionizing radiation, almost total lack of oxygen, and up to 1000 atm of pressure. When moisture levels return to normal, normal life functions resume.

Although they represent a relatively small percentage of the total species on this planet, metazoans have a major impact on

the biosphere. Early in the evolutionary history of metazoans, reef-building sponges and corals evolved, creating biogenic alterations in ocean current patterns and novel forms of habitat for additional life forms. Benthic metazoans make use of, and help maintain, the ocean bottom while annelids, nematodes, rotifers, and a variety of arthropods perform the same function for terrestrial soil systems. Many metazoans serve as habitat for other metazoans: in the life-cycle of an individual tapeworm, a copepod, a mollusk, a ray-finned fish, and an elasmobranch may all serve as habitat. The many metazoans that are filter or suspension feeders may act as bio-accumulators. In some cases, their activities may enhance local environmental quality, but this may be a mixed blessing. Oysters and other edible mollusks, for example, are excellent at extracting bacteria and other microbes from the water, but if those microbes include fecal coliform bacteria from human sewage the value of the mollusks as food is severely compromised. The array of complex ecological interactions between plants and insects has permitted the classification of insects as “beneficial,” meaning that they do not compete with us for plant biomass, “pest,” meaning that they do compete with us for plant biomass, or “vector” when they transmit diseases to us or our livestock. We use parasitoid insects as agents of biocontrol by infecting pests and vectors with them.

Summary

Organismal diversity is not just amazing, it is important. The extent to which parts of today’s planetary array of organisms can be reduced without creating a cascade of extinctions is unknown but hotly debated. As well, virtually every species has some value to humans, directly or indirectly. Organisms provide us with food, shelter, raw materials, things of beauty, and pharmaceuticals; help us with our work; and maintain the ability of our air, soil, and water to sustain life, including our own. They are valuable to us indirectly as the building blocks of the biosphere within which we originally evolved and which we still require in order to survive.

There is also clear evidence that all organisms are intimately tied together in the structure of the biosphere because they are all simultaneously parts of larger genealogical and ecological wholes. The significance of the duality of organismal diversity is most apparent in the recognition that new types of organisms are derived from preexisting organisms, while at the same time almost all organisms make extensive use of the biodiversity that predated their origins. Newly evolved organisms always have an impact on preexisting ones. Because it is in the nature of the organism to be relatively autonomous from its surroundings, these interactions are not necessarily positive, often taking the form of “conflicts of

interest.” The evolutionary resolution of these conflicts of interest has produced an increasingly complex biosphere. As Maynard Smith and Szathmari (1995) observed, each major transition in evolution has been associated with the emergence of organisms, and by extension the entire biosphere, with enhanced abilities to produce, maintain, and transmit information cohesively and also associated with the emergence of novel forms of selection resulting from the evolution of those new organisms. In this way, each newly evolved form of organism becomes intimately involved with both local and global ecology, maintaining the biosphere as a relatively isolated system with its own windows of viability (Ulanowicz, 1997).

Diversity, Taxonomic versus Functional

Glossary

Functional diversity A component of biological diversity that enumerates the different types of processes in a community that are important to its structure and dynamic stability.

Functional group A group of species that utilize similar resources; synonymous with *guild*.

Guild A group of species that utilize similar resources (usually food).

Species evenness A measure of the relative abundance of species in an area.

Species richness The number of species in an area.

Species turnover The change in the composition of species in an area due to the extinction of some species and the replacement by a new species through colonization.

Taxonomic diversity The number and the relative abundance of species in a community.

Species, Communities, and Ecosystems

Linnaeus (1735) and Hutchinson (1959) provided a convenient starting point to address biodiversity in terms of taxonomic and functional diversity. Linnaeus formalized the two-kingdom scheme of Plantae and Animalia and made the distinction between sessile photosynthetic plants and motile food-ingesting animals. Predating an understanding of photosynthesis or modern evolutionary theory, this work was descriptive and simply attempted to categorize and count organisms rather than posit mechanisms. Function was at the basis of the classification. In his address to the Society of American Naturalists, Hutchinson, like Linnaeus, made a deliberate distinction between primary producers and heterotrophs by asking "Why are there so many kinds of animals?" The unique feature of this address was that it studied biodiversity by invoking principles from ecology and evolution, formalizing niche theory, and including energetics. More important, it marks an early attempt to link species diversity to the functioning of an ecosystem.

The choice of taxonomic versus functional diversity illustrates a broader issue in science. In both cases, traditional taxonomies based on individual traits or ones based on the functional attributes of a species in a community or ecosystem are human constructions. Ehrlich and Holm (1962) summarized the dilemma nicely:

There seems to be no theoretical reason why there must be complete congruence among estimates of relationships based on characters from different developmental stages or on characters from different organs systems of the same stage.... In a taxonomy based on ecological requirements, whales will be more closely related to sharks than to bears. Such a relationship is no more or less "true" than the classical one: it is merely based on different attributes.

At some point, the question comes down to the type of information that is used, the way it is used, and why it is used. The transition from phylogenies based on taxonomies of morphological characteristics to ones based on taxonomies of genetic information have revealed ecological and functional coherence that Ehrlich and Holm (1962) envisioned for higher taxonomic rankings (phyla, orders, and families), if not for species.

Different Approaches to Studying Biodiversity

There are different subdisciplines within ecology: autecology (individual and population ecology), community ecology, and ecosystem ecology. The focus and approach of each subdiscipline and the type of information each uses have influenced the degree to which taxonomic or functional diversity have been used (Table 1).

Individual and Population Approaches

Autecology is the study of individual organisms. The approach originally focused on the adaptiveness of an organism's physiology to the environment but has since been expanded to include the study of the distribution and dynamics of populations. In terms of biodiversity, autecology has embraced taxonomic diversity.

The Community Approach

The community approach defines diversity in terms of the number of species and relative abundances of species. This information is used to study the effects of the number and types of interactions and the consequences that the interactions have on the distributions and abundances of the species and the dynamic stability of the community. Community ecology tends to focus more on taxonomic diversity than on functional diversity. An ideal description of a community would include all species and species interactions. In practice, descriptions of communities include a mixture of individual species and aggregations of species. The aggregations have been based on functional attributes defined by similarities in resource utilization among species and on taxonomic affinities (e.g., "mammals").

The Ecosystem Approach

The ecosystem approach defines diversity in terms of processes and function within the community. The focus is not on species *per se* but on the products of species interactions, usually different forms of carbon or nitrogen. Underlying this approach is the belief that species interact in ways that reinforce stabilizing feedbacks that operate to maintain a persistent steady state. The feedbacks operate through the availability of nutrients in one pool that are critical to another pool.

Table 1 Information used by different subdisciplines of ecology

	<i>Subdiscipline</i>		
	<i>Autecology</i>	<i>Community ecology</i>	<i>Ecosystem ecology</i>
Focus	Individuals and populations Species	Populations Species and guilds	Forms of matter Functional groups
Units	Individuals	Individuals	Biomass
Biodiversity	Taxonomic	Taxonomic and functional	Functional

A typical description of an ecosystem does not include many species (except for the dominant species) but rather aggregates of species that are similar in the ways in which they process matter relative to a key process. For example, the decomposition of pine needles on a forest floor is a complex process that is influenced by the nutrient quality of the pine needles, the temperature and moisture of the forest floor, and the organisms that are present. For the microbes alone, the process might involve more than 100 species of saprobic fungi and an equal number of strains of saprobic bacteria. Depending on the level of resolution desired, the microbes could be aggregated into a single pool of *decomposers* or separated into pools of *fungi* and *bacteria*. The justification for the seemingly casual treatment of the individual species is that the focus is not on how many species are present but on the general composition of the pool and the rate at which the pool processes matter.

Species, Function, and the Ecological Niche

Taxonomic and functional diversity use similar information but in different ways. The species is central to taxonomic diversity. Species are arranged into phylogenetic relationships that are based on how they acquire energy, their cell types, the level of cellular organization, their embryology and life history, their physiology, and their genetic makeup (RNA or DNA or both). Different classification schemes have been proposed that use all or some of these criteria with different weights given to any one of the criteria. Ecosystem processes are central to functional diversity. Functional diversity has been based on ecological characteristics. Species are aggregated into functional units based on how they use resources. Various schemes have been proposed to aggregate species into functional groupings. Species are arranged into functional relationships based on how they acquire energy, where they acquire energy, the rates at which they process energy (physiology), and when they process energy (life history).

Linking taxonomic and functional diversity would require integrating information that describes the makeup of an organism (its taxonomic characteristics) along with the rates at which it processes and transforms matter (its functional characteristics). Niche theory offers a way to link taxonomic and functional diversity.

The Ecological Niche

The ecological niche of a species has been defined by the resources it requires and by its role or function in the environment. The concept of the ecological niche when introduced by

Figure 1 Projection of eight species (A–H) onto two of the principal niche axes (food and time). (a) The ovals surrounding each species represent the region of the food and time space that each species occupies. Ovals that overlap one another represent regions in which the species share (compete for) resources. (b) Ecologists may aggregate species that occupy similar niche spaces into functional groups (species within the shaded ovals).

Grinnell (1917) focused on the habitat requirements of a species for it to survive and reproduce. Hutchinson (1959) expanded on this definition of niche by disaggregating the habitat into the multiple resources it embodied. The physical space a species occupies, the temperature and moisture conditions of the space, and the seasonality in abiotic and biotic conditions that the space experiences, along with the food requirements and the interactions that a species engages in with other species are considered. Here the niche of a species can be viewed graphically as an n -dimensional hypervolume in which each resource represents an independent axis (Figure 1).

The space that each species occupies within this hypervolume is defined by its basic resource requirements (i.e., the fundamental niche) and is winnowed down by antagonistic interactions with other organisms (i.e., realized niche). Schoener (1974) presented an analysis of the resource requirements for several species from different taxa, revealing that the principal niche axes are food, habitat use, and time.

Elton (1927) defined the ecological niche in terms of the role of a species in the environment. This definition is subjective but not at odds with resource-based definitions offered by Grinnell (1917) and Hutchinson (1959); rather, it is conditioned on them. The role, or in keeping with this article, function of a species is a property that emerges from the adaptations of species in meeting their resource requirements to survive and reproduce. As for information, both the requirements-based and functional-based definitions of niche are grounded in the genetics of the species, providing a means to link species diversity and functional diversity.

Functional Groupings of Species

Both the community and the ecosystem perspectives have grouped species into larger units when studying interactions among species or processes mediated by species. The schemes used have ranged from those of convenience, which are usually based on a broad taxonomic category, to ones that have adopted strict criteria that may include organisms from different taxonomic groupings. For this discussion, the groupings that have been based on the resource requirements of a species and its position in niche space relative to other species makes the most sense, given that function in an ecosystem context is directly related to how species utilize resources. Hence, a functional group is composed of species that utilize similar resources (i.e., the resource-based niche definition) and perform similar roles (i.e., the functional-based niche definition) in the environment (Figure 1). There is no standard number of resources (axes in niche space) used to establish functional groups, but many are based on the principal resources of food, habitat, and time. This has resulted in the groupings being given different names. For example, a *guild* is defined as a group of species that feed on similar food in a similar way. Soil ecologists define a *functional group* as a group of species that feed on similar food in a similar way, occupy the same habitat, and possess similar life histories.

Estimating Diversity

Procedures to estimate species diversity originated from the fields of information theory and statistics. If presented a code with a set number of symbols (s) of known proportions (p), it is desirable to estimate its information content. Ecologists simply substituted the species (or aggregations of species) for the symbols. Species diversity of a community could be estimated in the same way as the information content of a code. Two aspects of species diversity are the number of species (species richness) and the relative abundance of species in a community (species evenness).

Species Richness

Species richness (S) is the number of species within a defined region. The species richness of a region is obtained through sampling or via a census. Because “region” is defined by the observer, species richness has been further categorized into three components to account for changes in spatial scale.

Alpha diversity, sometimes referred to as *point diversity*, is the species richness that occurs within a given area within a region that is smaller than the entire distribution of the species. *Beta diversity* is the rate at which species richness increases as one moves in a straight line across a region from one habitat to another habitat. In other words, it is the rate of change in species richness that occurs with a change in spatial scale. *Gamma diversity* is the species richness within an entire region. As the area being surveyed approaches that of the entire region, alpha diversity approaches gamma diversity and beta diversity approaches zero.

Species Evenness

Species evenness takes into account the number of species and the relative abundance of species in a community. Several indices have been proposed. Two of the commonly used measures of evenness are the Shannon index (H) and the Simpson index (D).

The Shannon index (H) is a measure of the information content of a community rather than of the particular species that is present. The index is as follows:

$$H = - \sum_{i=1}^S p_i \log p_i$$

where s is the number of species in the community (species richness) and p_i is the relative proportion of species i . Hence, if two communities (A and B) with the same number of species (not necessarily the same species) present were compared, and the distributions of p_i were the same, then $H_A = H_B$. If either the number of species or the proportions differed, however, then $H_A \neq H_B$. In the latter case, the community with the greater number of species whose relative abundances were equal would possess the higher diversity.

The Simpson index (D) measures the dominance of a multispecies community and can be thought of as the probability that two individuals selected from a community will be of the same species. The Simpson index was originally proposed as follows:

$$D = - \log \sum_{i=1}^S p_i^2$$

where S is the species richness of a community and p_i is the relative proportion of species i . The index can be modified to $1-D$ to give it the property of increasing as diversity increases (the dominance of a few species decreases).

Linking Species Richness and Species Evenness

Species richness and species evenness are special cases of dichotomous-type rarity measures. For dichotomous-type rarity measures for a pool of s species, the rarity of species i , whose

function is denoted $R(p_i)$, depends only on its relative abundance (p_i). The rarity measures (Δ) take the following form:

$$\Delta = \sum_{i=1}^s p_i R(p_i)$$

The relationships between species richness (S), the Shannon index (H), and the Simpson index (D) are presented in **Table 2**. Notice that the indices share three important properties: (1) Δ is maximized when $p_i = 1/S$ for all i species; (2) given that $p_i = 1/S$, the community with the higher species richness has the greater diversity; and (3) $\Delta = 0$ if the community possesses a single species ($S = 1$).

Biodiversity and Systems Theory

One of the enduring tenets of ecology in the early part of the 20th century was that a diverse community was a stable community. The linkage between biodiversity and stability has an intuitive appeal. The more species there are in a community, the more likely they would be tightly networked, and hence the more stable the community would be. Interestingly, function plays an important role in this argument in that in a highly diverse community, there would be alternative species or assemblages of species to perform key tasks to sustain the cycling of matter and the current diversity. These ideas have been challenged and modified. Ecologists agree that biodiversity is important to the function and stability of an

ecosystem. The current debates concerns the nature of the relationship between biodiversity, function, and stability.

Although useful, the functions used to estimate biodiversity that were presented previously are descriptive measures and imply neither the mechanisms that shape biodiversity nor the importance of biodiversity to maintaining the structure and dynamic stability of a community. If the diversity of one community were higher than that of another, does this increase its likelihood of persisting in time or recovering from a disturbance? The answer depends on the species involved. For example, the colonization of an exotic species increases the species richness of a community but does not necessarily increase its stability – to the contrary, it often destabilizes the system. The addition of a predator, however, can stabilize an ecosystem by tempering the oscillations in the population densities of its prey through time. Biodiversity is a property of complex dynamic biological systems. The steady state and stability are two concepts important to the study of complex dynamic systems.

The Steady State

A steady state is an equilibrated condition in a dynamic process in which the rate of input of a state variable is equal to the rate of output of that variable (**Figure 2**). The dynamic process can involve any variable that changes in time. For taxonomic and functional diversity, the variables of interest are the number of species or functional groups, the densities and biomass of each species or functional group, and the mass of key elements within different pools within the ecosystem.

The Number of Species

The number of species in a community is at steady state when the rate of colonization equals the rate of extinction (**Figure 3**). The classic model of this process, the theory of island biogeography, assumes that the rate of colonization is affected by

Table 2 Rarity functions and forms of diversity indices

	Rarity function	Diversity index
Species richness (S)	$R(p_i) = (1/p_i) - 1$	$\Delta = S - 1$
Shannon index (H)	$R(p_i) = -\log p_i$	$\Delta = -\sum p_i \log p_i$
Simpson index ($1 - D$)	$R(p_i) = 1 - p_i$	$\Delta = \sum p_i(1 - p_i)$

Figure 2 Diagram and list of the processes (inputs and outputs) that contribute to the dynamics of a single state variable (X) or several state variables [X_i].

Figure 3 The effect of the rates of colonization and extinction on the species richness of large and small islands (S_L and S_S , respectively). T_L and T_S represent the points at which the rates of colonization and extinction are equal. Adapted from MacArthur RH and Wilson EO (1967) *The Theory of Island Biogeography, Monographs in Population Biology*, vol. 1. Princeton, NJ: Princeton University Press.

how far the habitat being colonized is from the source of species and by the size of the habitat being colonized. Colonization rates are higher for large habitats that are close to the source of species than for smaller distant habitats. The rate of extinction is affected by the size of the habitat. The rates of extinction for smaller habitats are higher than those for larger habitats.

Species Composition

In the model presented previously, although the number of species is constant at steady state, the species composition of the community does not remain constant. The model simply assumes that once the rates of colonization and extinction are equal, then for every new species that enters a habitat, one of the current resident species goes extinct. This point is important when trying to estimate the diversity of a habitat by sampling the habitat over time. If a habitat were sampled long enough, the estimate of the number of species within the habitat would equal the number of species in the habitat serving as the source, even though the source has a higher number of species at its steady state than the habitat being colonized.

Population Densities

The population density of an individual species within a habitat is at steady state when the number of births and immigration equal the number of deaths and emigration. When modeling this process, ecologists typically assume that the habitat is closed to immigration and emigration and focus entirely on the rates of birth and death. More sophisticated approaches that involve multiple habitats will include the immigration and emigration of species among habitats.

Community Structure

A community is at steady state when the species composition of the community and the densities of the species remain constant. This implies that the species richness and evenness of the community do not change. This condition is rarely met since the species composition and the densities of the species fluctuate through time.

Figure 4 The relationship of various ecosystems in terms of their community production (grams per square meter per day), P , and community respiration (grams per square meter per day), R . The dashed line represents the steady state in terms of P and R ($P/R=1$). Note the position of the disturbed ecosystems.

Ecosystem Processes

An ecosystem process is at steady state when the rate of input of matter or energy is equal to the rate of output. The input of matter and energy occurs via photosynthesis and from sources external to the ecosystem (e.g., leaves entering a stream). The export of matter and energy occurs through heterotrophic respiration and the physical movement of matter from the ecosystem (e.g., export of leaves from forest to a stream). The production of organic matter from inorganic matter (photosynthesis) and the transformation of organic matter to other organic forms and inorganic matter (heterotrophic respiration, hereafter referred to as *respiration*) are ecosystem processes that approach a steady state and illustrate the interplay between matter and energy. When the rate of photosynthesis equals the rate of respiration, the system is said to be at steady state (Figure 4). In other words, at steady state the ratio of production to respiration for matter and for energy is 1 ($P/R=1$).

Stability

A population, community, or ecosystem is stable if it can persist through time and can recover from minor disturbances. A disturbance is any perturbation to the system that causes any of the species or functional groups to deviate from their steady state. There are many facets to stability and many operational definitions as well. Aspects of stability include local asymptotic stability and short-term transient dynamics.

Local Asymptotic Stability

An ecosystem possesses local asymptotic stability if over time it returns to its original steady state following a minor disturbance. The minor disturbance is relative to the sizes of the populations involved and occurs in the neighborhood of the steady state, hence the reference to "local." This concept of stability has been widely used by biologists because it is simple and exact in its interpretation. It has been criticized for the same reasons that it has been accepted. For example, high species diversity has been shown to negatively impact the local

stability of model ecosystems. This result was the basis for the hypothesis that dynamic stability constrains biodiversity. However, competing models of ecosystems with different sets of assumptions and criteria for stability, although they do not disagree that dynamic stability affects biodiversity, yield different results with regard to the nature of the relationship.

The concepts of local stability and the theory of island biogeography may seem at odds with one another, even though they rely on similar mathematics and assumptions and are modeling the same systems. An obvious question is, how can an ecosystem be locally stable if the species composition of the ecosystem is changing? The discrepancy can be clarified by revisiting the processes that are being modeled. When modeling populations within a community, local stability is in reference to the densities or biomass of the populations. The dynamics of the populations are governed by the difference between the rates of birth and death. When modeling the species diversity within the same community, local stability is in reference to the number of species that are present. The dynamics of the number of species is governed by the rates of colonization and extinction. To carry this a step further, the local stability of the carbon or nitrogen cycles within an ecosystem is in reference to the mass of the different forms of carbon or nitrogen. The dynamics of the different forms is governed by the functional attributes of the species present and the rates at which the different forms are acted on.

Transient Dynamic Behavior

Transient dynamics represent the short-term dynamic behavior that asymptotically stable systems exhibit following a minor disturbance. The nature of and degree of the transient response can influence the stability and diversity of the system. Transient behavior includes the amplification and decay of a perturbation, represented by an amplification envelope, $\rho(t)$, encompassing the magnitude and extent of the deviation and its temporal components (Figure 5). Following a disturbance, the perturbation to the system, now portrayed as deviations from equilibrium, amplify to a maximum $\rho_{\max}$ at time $T_{\max}$, with a rate defined by its reactivity during the short-term transient phase.

Eventually, the perturbation decays to the long-term asymptotic phase at a time defined by its return time at a rate defined by its resilience. The principle of resilience can be applied to any state variable present in an ecosystem: population densities, the number of species, or the mass of nutrients. Resilience is a function of the rates of inputs of the state variables, the rate at which the state variables turn over, and the number of state variables. The return time of a system is a measure of its resilience and is estimated as the time between the point when the disturbance altered the ecosystem and the point at which the ecosystem recovers. More resilient ecosystems have shorter return times than less-resilient ones.

The persistence of a system and hence its diversity may be compromised if the system possesses a highly reactive transient phase or if the frequency of disturbance is too great given the length of return time because a system may not have time to recover from any one incident. Under these circumstances, the perturbations may grow initially and the populations may oscillate wherein the densities of individual species may approach zero, making them vulnerable to future disturbances, or some may dip below a lower threshold where the

Figure 5 An overview of transient dynamic behavior. (a) The transient dynamics of a multispecies system that has been disturbed as it returns to equilibrium. (b) A summary of the components of the transient behavior of a reactive system in terms of the amplification envelope $\rho(t)$ through time. The deviations from equilibrium amplify to a maximum $\rho_{\max}$ at time $T_{\max}$ with a rate defined by its reactivity (slope of —) during the short-term transient phase. The disturbance eventually decays at a rate defined by its resilience (slope of - - -) to the long-term asymptotic phase at a time defined by its return-time. Adapted from Chen XIN and Cohen JE (2001) Global stability, local stability, and permanence in model food webs. *Journal of Theoretical Biology* 212: 223–235.

likelihood of successful reproduction is compromised. Frequent disturbances of reactive systems may also push the system and its dynamic state from one state and attractor to another. Again, although there is uncertainty of the effects of this type of transition on the system, a consequence is the loss of species or the introduction of new species.

Modeling Species Interactions

A simple mathematical exercise illustrates how the number of interacting units (species) within a system and the number of interactions between these units (species interactions) are related to the stability of the system. The exercise constructed simple systems of four, seven, and 10 units assumed to be at a steady state. For a system of a given size, connections are made between the units in a way that ensures that all units would be connected to the system, creating several variations of the system in terms of the connections. Next, the strength of the connections is allowed to vary, and the systems are disturbed by moving the units away from their steady state. Two results emerge from this exercise. First, as the number of interacting units increase within a system the likelihood of the system returning to a steady state after a small disturbance (stability) decreases. Second, for a given number of interacting units, as the number of connections between the units increases, the stability of the system declines.

There is a clear connection between the simple mathematical exercise previously presented for estimating diversity

and the diversity and stability of ecological communities. The species is substituted for the generic units modeled previously, and the interactions are defined in terms of predation, competition, or mutualism. Like the generic modeling exercise, high biodiversity does not necessarily lead to stability. Additional study demonstrates that systems composed of species aggregated into blocks of highly interactive species that are connected by weaker interactions are more stable than systems with the same number and types of species and interactions arranged at random. Hence, the way in which the community is constructed affects its diversity and stability.

The types of interactions among species affect the stability of a community as well. Theory and observation agree in general terms on this point, if not on specifics. For example, mutualistic interactions, whereby the actions of each species benefit the growth and dynamics of one another, and omnivory, in which species derive energy from different trophic levels, have been shown to be destabilizing in simple models, but both are prolific in natural communities. All the dominant terrestrial ecosystems rely on a mutualism between the vascular plants and microbes, and nearly every described ecosystem possesses numerous examples of omnivory.

Modeling Species and Processes

Process-oriented models focus on the transformation of elements among various inorganic to organic states through ecosystems. Carbon, nitrogen, and phosphorus are the more common choices of elements to be modeled given their importance to plant and animal growth. Models of species interactions have been connected to models of processes. The general approach to linking these models is to use the structure and formulation adopted when modeling species with the currency used in models of processes. First, species are aggregated into functional groups using one of the schemes described previously, and the interactions among the functional groupings are established. Second, the biomass (expressed in terms of carbon, nitrogen, or phosphorus) of each functional group is estimated. Third, a series of differential equations is developed that establishes which functional groups interact with one another and the nature of the interactions. Parameters within the models include birth and death rates, feeding rates, and the efficiencies by which the functional groups convert consumed matter into new biomass. The models are used to estimate the flow of elements among the functional groups, the flow of elements out of the system, the stability of the ecosystem, and the resilience of the ecosystem.

The following results have emerged from these models: First, the models are sensitive to the changes in the parameters associated with the physiology and life histories of the species within the functional groups. For example, microbes possess high reproductive rates and high rates of energy conversion, and they process matter at a higher rate compared to a functional group dominated by arthropods or nematodes, which possess lower reproductive rates and rates of energy conversion. Second, functional groups are arranged into interactive blocks that form pathways of material flow that originate from a specific source and end with a top predator. The blocked arrangement of functional groups, the distribution of biomass within the ecosystem, and the distribution

of the flow of elements through the ecosystem influence the stability and resilience of the system.

Linking Taxonomic and Functional Diversity

The linkage between taxonomic diversity and functional diversity involves many facets. The morphology of an organism determines the type of habitat in which it resides and its ability to colonize new habitats. The physiology of a species influences its adaptiveness to a habitat and the rates and efficiency with which it transforms matter. The life history of an organism influences the rate at which it processes matter (births, deaths, and consumption). Linking taxonomic diversity to functional diversity requires finding measurable attributes that all organisms possess that have meaning to all the ecological subdisciplines, but it also requires flexibility in terms of how the information is used. Three case studies are presented in the following sections. The case studies illustrate how, when studying biodiversity, aspects of both taxonomic and functional diversity are used interchangeably.

Diversity of C3 and C4 Grasses

The first case study involves a comparison of the distribution of grass species that possess either the C3 or C4 photosynthetic pathways in North America. The study illustrates how the information of autecology can be used to find mechanisms to explain patterns in diversity. The study demonstrates how the functional aspects of an organism's physiology influence a species adaptation to a habitat and ultimately the diversity of species with similar physiologies.

Plants that possess C3 and C4 photosynthetic pathways differ in terms of their morphology and biochemistry as they relate to the dark reaction of photosynthesis. For C3 plants, photosynthesis occurs entirely within the outer mesophyll cells, in which CO₂ enters the Calvin–Benson cycle through the plants' stomata. The enzyme (RuBP carboxylase or Rubisco) that incorporates CO₂ into the Calvin–Benson cycle also has an affinity toward O₂. If O₂ were incorporated instead of CO₂, the plant would experience photorespiration – energy is expended, no carbon is fixed, and the plant loses organic carbon. For C4 plants, there are two types of photosynthetic cells: the outer mesophyll cells and the inner bundle sheath cells. In C4 plants, CO₂ enters the mesophyll through the stomata and is incorporated into a four-carbon compound before being exported to the bundle sheath cells in which it enters the Calvin–Benson cycle. The additional steps that occur within the C4 plants prior to the Calvin–Benson cycle cost the plant additional energy and organic carbon. However, the enzyme (PEP carboxylase) that adds the CO₂ to the four-carbon molecule in the mesophyll cells is more efficient than Rubisco and less likely to initiate the loss of organic carbon to photorespiration. This trade-off places plants with the C4 pathway at a disadvantage under cool and moist conditions compared to those with the C3 pathway, but it affords them an advantage in warmer and dry conditions.

Within North America, the northern latitudes are dominated by species of C3 grasses, whereas the southern latitudes are dominated by species of C4 grasses. This pattern of

Table 3 Functional groups of arthropods by number and relative proportion (%) on islands before and 1 year after fumigation

	Number and relative proportion (%)							Total
	Herbivore	Scavenger	Detritivore	Wood borer	Ant	Predator	Parasite	
Before	55 (34)	7 (4)	13 (8)	8 (5)	32 (20)	36 (22)	12 (7)	163
After	55 (40)	5 (4)	8 (6)	6 (4)	23 (17)	31 (23)	9 (6)	137

diversity has been attributed to the adaptiveness of each pathway to patterns of temperature and light intensity. The lower latitudes possess higher temperature and higher light intensity than the upper latitudes given the orientation of Earth to the sun. Grasses that possess the C3 pathway have been shown to be more productive than those with the C4 pathway under conditions of cool temperature and low light intensity. At higher temperatures and light intensity, C3 plants suffer greater water loss through their stomata and increased photorespiration than do C4 plants.

Test of the Theory of Island Biogeography

This case study illustrates how information from the community perspective has been used to study biodiversity. The experimental manipulations of several small mangrove islands off the Florida coast by Simberloff and Wilson (1969) and the reanalysis of their work by Heatwole and Levins (1972) offer not only the best validation of the theory of island biogeography but also some insight into how taxonomic diversity and functional diversity are related.

The arthropods on four small mangrove islands were surveyed. The islands were then fumigated with methyl bromide to eliminate the arthropods. For 2 years following the disturbance, the islands were resurveyed for arthropods to capture the recolonization process. The results were consistent with those predicted by the model proposed for the theory of island biogeography (Figure 3). The colonization rates were higher and the steady states in species richness were achieved sooner on islands closer to the mainland than on the more distant island. Once a steady state in species richness was achieved, the species composition changed due to the predicted turnover in species.

The study provides an explicit link between the recovery process, species diversity, and functional diversity when the colonization of functional guilds – groups of species that share common food and foraging behaviors – is compared to that of the individual species. One year following the fumigation, the taxonomic diversity of the islands was lower than it was prior to the fumigation (Table 3). However, the proportion of species within each of the guilds was the same as it was prior to fumigation. These results suggest that the functional diversity of the islands recovered before the species diversity. In other words, the taxonomic diversity of the communities was in some way dependent on functional characteristics of the community.

Invasion of an Exotic Species

The final case study illustrates how elements of taxonomic and functional diversity and information from autecology,

community ecology, and ecosystem ecology have been used to study biodiversity. Vitousek *et al.* (1987) studied the natural history of the invasive plant species *Myrica faya* and the effects that it has had on the nitrogen cycle and plant community development of recent lava flows in Hawaii. Since its introduction to Hawaii from the Canary Islands by Portuguese immigrants at the end of the 19th century, *M. faya* had colonized more than 34,365 ha. *Myrica faya* forms a symbiotic association with the soil nitrogen-fixing actinomycete, *Frankia*. The plant possesses two characteristics that separate it from the native nitrogen-fixing plants on the islands. Unlike the native plant nitrogen fixers (*Acacia koa* and *Sophora chrysophylla*), the seeds of *M. faya* are small, have an edible fleshy fruit, and pass through the digestive systems of birds intact. Moreover, *M. faya* is a more efficient nitrogen fixer than the native species. When combined, these factors make *M. faya* a superior colonizer of recent lava flows, pastures, and forests.

Once established, the *M. faya* and its soil symbiont, *Frankia*, alter the nitrogen status of the soils. For example, soil nitrogen inputs within open canopies of *M. faya* were four times more than those of similar sites without the exotic plant (23.5 and 5.5 kg per ha per year, respectively). The added soil nitrogen was shown to facilitate invasions by other exotic species (e.g., strawberry guava, *Psidium cattleianum*) to the detriment of native plant species. The functional attributes of a single species and its symbiont affected the biodiversity of a community by altering the course of community development.

Ecological Coherence of High Taxonomic Ranks

The acquisition and disposition of matter and energy are key processes that all organisms possess that directly link them to ecologically relevant functions. The case studies previously presented share this common feature. The acquisition of matter and energy are characteristics of the interactions in question, and they occur or emerge at taxonomic ranks higher than species. This should not be too surprising given that the modern phylogenies developed from the times of Linnaeus (1735) through Whittaker (1969) relied on energy acquisition and morphology (which is related in many ways to energy acquisition). Recent treatment of prokaryotes that are based on gene sequences have entertained this idea of including environmental information into the calculus of forming taxonomic clades. Assessments of bacterial and archaeal phylogenies when viewed through this lens confirm that there appears to be greater ecological coherence of organisms at high taxonomic ranks. Reducing ecological diversity to functional groups of species that share these attributes may in fact

be the way to organize information captured within species to make the connection between functional and species diversity.

Natural Selection

Species evolve and communities and ecosystems change, but do communities and ecosystems evolve? Does natural selection operate on communities and ecosystems even though they do not possess genes? Natural selection needs to be defined before these questions can be answered. Natural selection is the differential perpetuation of genes in successive generations caused by different degrees of adaptiveness to the environment.

One argument is that ecosystems do evolve because the composition of species within a community changes and natural selection operates on the gene pools of each species. In addition to the changes in the genetic makeup of the species, there are changes in key processes that feed back to reinforce stable configurations or that initiate change. A criticism of this analogy is that natural selection at the ecosystem level for the type of coordination among species that leads to a stable ecosystem is not the same as selection at the organismal level on genes. Selection on genes operates through differential reproductive success of individuals, whereas this may not be true at the ecosystem level since the boundaries of an ecosystem are not so clearly defined.

An alternative view posits that ecosystems do not evolve but that the species composition of the stable ecosystem is a result of the selection operating on individuals and the coevolution of species interacting with one another. The outcome of selection on individuals can influence function within a community, which in turn feeds back as a form of selection. Unique to this argument is that the adaptiveness of a species includes the degree to which its dynamics and function contribute to and are compatible with the stability of the ecosystem as a whole.

Glossary

Convergent evolution Distant or unrelated organisms evolve the same anatomical, morphological body plan characteristics, or ecological function.

Ecosystem The combined plant and animal communities plus their physical environment.

Ecosystem function The energy flow, productivity, element cycling, and resilience of ecosystem structure; synonymous with “behavior of ecological systems” and “ecological processes.”

Ecosystem structure The organisms, their communities, biodiversity, and habitats that comprise an ecosystem.

Functional groups Polyphyletic suites of species that share ecological characteristics and play equivalent roles in natural communities and ecosystems. Commonly, organisms with convergent anatomical, morphological, physiological, behavioral, biochemical, or trophic characteristics are grouped together.

Guilds Organisms that use similar resources in similar ways. Depending on the application, guilds can be synonymous with functional groups.

Functional Groupings and their Utility

More than 40 years ago, ecologist and evolutionary biologist G. E. Hutchinson wondered why there were so many kinds of species. This question engaged many of the most powerful minds in ecology and the natural sciences. It launched decades of research, brought us the concept of ecological niche and considerable ecological and evolutionary theory, and is the focus of many articles in this encyclopedia. Much less has been written about an equally compelling question: Why are there so few kinds of morphologies or physiologies, and what might the ecological consequences of such limits be? It also raises new questions, such as the following: Are there limits to the possible number of variations on any given body plan? Are there similar limits to the functional attributes of species and suites of species? Can functional attributes of species be abstracted such that their ecological roles can be inferred? Can several species fulfill the same functional roles? In other words, are species replaceable such that there are ecologically equivalent or redundant species? The answers to these questions have profound implications to how we view the natural world and possibly how we can conserve it. For example, does the extinction or extirpation of any given species degrade natural ecosystems in tangible ways?

Biodiversity includes the diversity of organic life on Earth and how it functions. How organisms “make their living,” how they interact and contribute to the ecosystem, relates to the functional properties of biodiversity. Functional groupings are polyphyletic suites of species that share ecological characteristics. Commonly, organisms with convergent anatomical, morphological, physiological, behavioral, biochemical, or trophic characteristics are grouped together. Functional properties may correspond to different ecological characteristics depending on the question being asked. They can include the habitats in which they live, the biomass or structure they

impart to a community, the rates at which they grow (their productivity), the rates at which they lose biomass (i.e., disturbance), the organisms they consume, the organisms that consume them, and their numerical or mass-specific importance to their communities or ecosystems. A functional group analysis can be applied more broadly in space for making biogeographic comparisons and in time for reconstructing paleocommunities than is possible at the level of species or of related taxa.

I explore functional groupings first from the perspective of the evolution of functional similarities, and then I discuss what functional groupings might mean to the structure and function of communities and ecosystems. I draw heavily, but not exclusively, on examples from the marine realm, in which there is the greatest phyletic diversity, longest evolutionary history, and clearest fossil record of how organisms and assemblages have evolved. Other extensive works on the topic of functional groups, such as that by Schluzer and Mooney (1994a), are exclusively terrestrial in their approach.

Functional distinctions can be based on any characteristic shared among organisms, such as morphology, physiology, or behavior. These are not independent features of organisms. An organism's morphology can influence its behavior and its physiology. Functional groupings would be unnecessary if organisms' taxonomic relationships corresponded well with their functional roles. However, functional characteristics are often decoupled from even closely related species, and thus the relationship between taxonomic relatedness and functional groupings warrants consideration.

Decoupling Relatedness from Functional Similarities

Species that are closely related evolutionarily are not necessarily morphologically or functionally similar. Conversely, just

because organisms are distantly related does not mean they are morphologically or ecologically different. There are examples of unrelated, or distantly related, organisms having similar morphologies, anatomies, behaviors, physiologies, and functional roles in natural communities. Such convergent functional properties are well-known and operate at many levels. Obviously, bats are flying mammals that exploit some of the same habitats and foods as some birds and moths. Squid are swimming mollusks that exploit some of the same habitats and foods as fish. Although bats are not perfect substitutes for birds, nor are squid identical to fish, their phyletic relationships tell us little about the ecological roles or functional characteristics they possess.

Although most closely related organisms share traits with the clade from which they evolved, and thus will tend to be functionally similar, this is not always the case. For example, hermit crabs are relatively small, anomuran decapods with an exposed, asymmetric abdomen that requires protection from unoccupied snail shells. They differ morphologically from true crabs, the brachyurans that have abdomens protected by a shield-like cephalothorax or carapace that also covers their walking legs (Figure 1). True crabs can attain large size. However, hermit crabs are very closely related to the morphologically distinct anomuran king crab (Figure 1). King crabs convergently evolved many of the characteristics of true brachyuran crabs; they are large and their abdomen is protected by a broad shield-like cephalothorax. Therefore, phylogenetically related king and hermit crabs are morphologically different, whereas phylogenetically distant king and true crabs are morphologically similar.

Morphological similarities can translate to functional similarities. In shallow coastal habitats of the Gulf of Maine, there are four species of large, clawed, decapods that live together and feed on the edible blue mussel, *Mytilus edulis* (Figure 2). The two most closely related species are *Cancer irroratus* and *Cancer borealis*. Both are brachyuran crabs in the family Cancridae. The third brachyuran crab, *Carcinus maenas*, is in the Portunidae family. However, the two distantly related crabs, *Carcinus maenas* and *C. irroratus*, share functional characteristics of small body and chelae ("claws") size while being behaviorally flexible, quick, and dexterous. They characteristically chip the perimeter of mussel shells at many

Figure 1 Phylogenetically related anomuran hermit crab (*Pagurus*) and king crab (*Lithodes*) are morphologically dissimilar. The distantly related brachyuran crab (*Mithrax*) is morphologically similar to the king crab (Reproduced from Cunningham CW, Blackstone NW, and Buss LW (1992) Evolution of king crabs from hermit crab ancestors. *Nature* 355: 539–542.).

locations to gain access to the food. Conversely, *C. borealis* and the lobster *Homarus americanus* share functional characteristics of large body and chelae size while being behaviorally constrained, slow, and strong (Figure 2). These two decapods characteristically crush mussel shells in the middle of the shell by applying brute force to the center of the shell. Therefore, the two most closely related crabs are functionally dissimilar and the two sets of most distantly related crabs (*Carcinus maenas* and *C. irroratus*) and other decapod groups (*C. borealis* and *H. americanus*) are both functionally similar.

Even within species, large functional differences exist. Amphibians such as frogs begin life as tadpoles with diets and habitats different from those of adults. Ferns and algae have ecologically distinct haploid and diploid phases. The heteromorphic range in some marine algae is striking. For example, the brown (Phaeophyta) algal kelp *Macrocystis pyrifera* can exceed 40 m in length and forms forests in its sporophyte ($2n$) phase but is a microscopic filament in its gametophyte ($1n$) phase. Some red algae (Rhodophyta) alternate between encrusting and erect phases; some green algae (Chlorophyta) alternate between endolithic microscopic and filamentous phases. Some habitats only support one phase. Each of these different ontogenetic and ploidy phases has strikingly different ecological properties, and differences within species can be greater than some differences among species. Therefore, knowing the species does not always provide insight into how the organism functions ecologically.

There are distinct limits to variety in morphology or important ecological function that are independent of biodiversity. Some characteristics, such as body size, are biomechanically limited; therefore, depending on the biomaterials available to an organism (i.e., cellulose, chitin, calcium carbonate, or bone), their morphology and the environment in which they live may limit their ecological

Phylogenetic vs Functional Characteristics

Figure 2 Phylogenetically related *Cancer* species are functionally different. The phylogenetically distant *Cancer borealis* and *Homarus americanus* are functionally similar (Reproduced from Moody KE and Steneck RS (1993) Mechanisms of predation among large decapods crustaceans of the Gulf of Maine coast: Functional vs phylogenetic patterns. *J. Exper. Marine. Biol. Ecol.* 168: 111–124.).

functions. These relationships are well described in works such as Thompson's (1966) *On Growth and Form*, Peter's (1983) *The Ecological Implications of Body Size*, or Niklas's (1994) *Plant Allometry*. Arguably, size and shape are prime determinants of many functional groupings of both plants and animals. Predators generally scale with, or are larger than, their prey. Thus, organisms constrained to small size are likely to be more vulnerable to predators and rarely if ever are "apex predators" in an ecosystem or community. Insects are a good example. They also illustrate the disconnect between species diversity and morphological variety. Insects account for most of Earth's biodiversity, but they are all relatively small. In contrast, most vertebrates are much larger (especially mammals and dinosaurs) and their biomass distribution does not overlap that of insects. Despite their long evolutionary history, there are no cow-sized insects, nor are there insect-sized cows. Body size constraints among insects occur because, among other reasons, their respiration is relatively inefficient and limited by their open circulatory system and trachea. Other factors, such as the composition of their exoskeleton, further constrain morphological evolution and the habitats into which they can and have radiated. Although insects have radiated impressively into terrestrial systems, they are virtually nonexistent in the marine realm. Thus, three-fourths of all species are insects, but three-fourths of the habitable space is devoid of them. There are morphological and functional limits to diversity.

Functional Changes in Assemblages over Evolutionary Time

Ultimately, the environment controls the distribution, abundance, and body plans that live in it. Evolution at several levels generates diversity of form and function, but the environment filters it. Constraints to diversification are many and relate to the environment as it changes and how organisms deal with it.

The history of life on Earth is punctuated with significant functionally novel additions to biotic assemblages. An excellent example of a functional group effect on global-scale ecosystem function is the cyanobacteria that began oxygenating the atmosphere more than 3 billion years ago. Biologically available oxygen began increasing approximately 1.4 billion years ago and is coincident with (and possibly necessary for) the evolution of the first metazoans. Still higher levels of oxygen may have been necessary for the Cambrian "explosion" of small shelly fauna. The sudden polyphyletic and global appearance of hard skeletal material (chitin and calcium carbonate) allowed for the evolution of large body sizes, efficient mobility, teeth, and defenses against predators. The structure and functioning of life on Earth changed at this time. Organisms functionally similar to those alive today first appeared. Since then, during the past 600 million years, there have been several biotic revolutions.

Decoupling phyletic evolution from functional group evolution is important. All but one of the major phyla may have evolved at or near the Precambrian–Cambrian boundary in as few as 25 million years. Alternatively, some argue that phyla evolution may have occurred much earlier (1 billion

years ago) as minute and embryonic or larval-like organisms and thus not recognizable by today's criteria. If this latter theory is correct, it would be a clear case of phyletic evolution being disconnected from the functional/morphological (phenetic) evolution that occurred 400 million years later. Despite the Cambrian (or earlier) origin of most major phyla, functional evolution and the filling of unexploited habitats ("ecospace" *sensu* Bambach, 1985) took considerably more time. Throughout the Paleozoic, morphological evolution and the filling of unoccupied habitats occurred episodically and polyphyletically, beginning with small surface deposit feeders and low-profile suspension feeders, progressing to greater depths into sediment and new epifaunal heights. The progressive utilization of three-dimensional space called "tiering" is thought to have contributed substantially to the global diversification in the early Paleozoic (Figure 3). The diversifying continued into the pelagic realm and into the sediment habitats (infaunalization) and recently included the radiation of large-bodied predators.

This pattern of diversification is composed of three relatively distinct faunas, each characterized by its own characteristic dominant taxa (Figure 3A), initial rates of diversification, and "equilibrium" diversity. Each fauna was functionally different. Surface deposit feeders such as trilobites and monoplacophorans dominated the Cambrian fauna, whereas the Paleozoic fauna radiated into and relied heavily on the pelagic realm. For example, the taller suspension-feeding crinoids of the Paleozoic fauna joined near-benthos suspension-feeding brachiopods, anthozoans, and stenolomate bryozoans and pelagic groups such as cephalopods and graptolites as dominants of this fauna. There were no known macroalgal grazers in the Paleozoic, and large stands of macroalgae were probably common. Sand habitats were virtually devoid of infauna. In contrast, the modern fauna included the rise to dominance of large invertebrate and vertebrate predators and herbivores. These included predatory neogastropod snails, malacostracan crab and lobsters, and at least four groups of swimming vertebrate predators among the bony fishes (Osteichthyes), dinosaurs (Reptilia), sharks (Chondrichthyes), and cetaceans (Mammalia, i.e., dolphins and whales). Most modern groups of fish (e.g., most modern reef fish) evolved at this time. Explanations for why large-scale changes occurred at the family level are complex. Organisms such as small deposit feeders may have suffered higher extinction rates as more mobile and more pelagic organisms with larger gene pools replaced them. A global crisis in the water column contributed to the most severe extinction event at the end of the Permian. Therefore, suspension feeders, pelagic organisms, and organisms with pelagic larvae suffered the highest extinction rates. This extinction caused a sharp decline in several of the dominant families of the Paleozoic fauna and marked the transition to the dominance of the modern fauna (Figure 3B). Prior to the dominance of the modern flora there were virtually no shell-crushing carnivores. Several groups of shell crushers, such as true brachyuran crabs, evolved in the Cretaceous and became important predators. Deep-grazing herbivores also evolved among the modern fauna. They created a uniquely intense level of grazing pressure which may have denuded many shallow marine habitats of macroalgae.

Figure 3 Faunal changes during the past 600 million years. (A) Three faunas with representative dominant animals. (B) Cumulative pattern of diversification of the three faunas. Arrows identify mass extinction events (Sepkoski, 1984). Each fauna represents dominance by a functionally distinct group. The Cambrian fauna were surface deposit feeders, the Paleozoic fauna were dominated by suspension feeders, and the modern fauna were dominated by large predators and protected prey. Note that the Paleozoic fauna was particularly susceptible to mass extinctions resulting from disruptions of the water column.

The Sudden Origin of Functionally Distinct Organisms and Then Functional Stasis

Functional evolution in the marine realm is striking. The transitions from surface-dwelling deposit feeders to a range of suspension feeders, to organisms using vertical space, and to big predators and herbivores represent significant functional changes over evolutionary time. There were also terrestrial revolutions in organism function. Angiosperms displaced functionally similar conifers and evolved functionally unique weeds. Pollinating insects and angiosperms coevolved and diversified. Obviously, the history of life is punctuated with the sudden appearance of functionally unique organisms that often change the biotic world.

Often, functionally unique groups change little over evolutionary time. Among marine invertebrate herbivores, there are only a few capable of biting into limestone or calcium carbonate. These herbivores leave a grazing trace fossil that allows for functional interpretations to be made over evolutionary time. Three groups known to excavate calcium carbonate are regular echinoids (sea urchins), true limpets (Patellogastropoda), and chitons (Polyplacophora). Trace

fossils from the Cretaceous (approximately 70 million years ago) reveal that each of these groups grazes distinctively with the same graze marks and to about the same depths into calcium carbonate as their modern counterparts (Figure 4). Although considerable variation exists within groups of herbivores, the differences among groups are much greater. Echinoid sea urchins have a characteristic intensity of grazing that is much deeper than that of chitons and limpets which are very distantly related but have similar shallow bites into calcium carbonate. In all cases, the first trace fossils known show these invertebrates biting the surface of calcium carbonate with the pattern and the depth into the substrate as they produce today. There appears to be little or no functional change in how they graze after the group first evolved. There are other examples. Predatory gastropods that drill their shelled prey have not changed their mode of attack since they first evolved in the Triassic more than 200 million years ago. Many limb and running characteristics between terrestrial vertebrate predator-prey interactions have also been shown to be remarkably stable over evolutionary time. This suggests that among these consumers and within established clades, there is functional stasis over evolutionary time.

Figure 4 Comparison of modern and ancient limpet graze marks on calcium carbonate substrates. (A) Modern limpet, *Tectura testudinalis*, grazing calcareous algae (scale bar = 0.5 mm) (Reproduced from Steneck RS (1982) A limpet coralline alga association: Adaptations and defenses between a selective herbivore and its prey. *Ecology* 63: 507–522.). (B) Cretaceous (more than 65 million years ago) limpet, *Radulichnus* sp. (scale is the same as in A) (Reproduced from Crimes TP and Harper JC (1977) *Trace Fossils 2*, Geological Journal, Special Issue No. 9. Liverpool, UK: Seel House Press.).

Functional Convergences

Convergent evolution results in distantly related organisms converging on the same body plan or ecological function. Charles Darwin noted in his *Origin of Species* (1859) that

for animals belonging to two most distant lines may have become adapted to similar conditions, and thus have assumed a close external resemblance; but such resemblances will not reveal—will rather tend to conceal—their blood relationship (page 463).

Relatively few convergently evolved anatomical, morphological, or physiological characteristics are the cornerstones of functional groupings.

Groupings among Mobile Organisms

Convergent evolution is well-known and documented in the terrestrial realm. Marsupial and placental mammals have converged to similar morphologies and ecological function (Figure 5). The limited variations on the mammalian body plan are evident in the wolf and catlike carnivores, the arboreal gliders, fossorial herbivores, anteaters, and subterranean insectivores that evolved independently in Australia for the marsupials and on the other continents for the placentals.

Convergent functions can be found among dissimilar-looking organisms. Distantly related marine molluscan herbivores, chitons and limpets, provide an excellent example. Chitons (class Polyplacophora) and snails (class Gastropoda) evolved in the Cambrian at the beginning of the molluscan diversification. The true limpets, Patellogastropoda, evolved from the Archaeogastropoda, much later in the Triassic. However, the radula (the teeth) of these two groups are functionally similar (Figure 6). Both groups have relatively few teeth that contact the substrate, and those that do are hardened by mineralization of iron or silica compounds (note the black teeth in Figure 6). Both groups have strong buccal

musculature for applying downward forces. Within the molluscan body plan, only chitons and limpets have such a large foot area-to-mass relationship and an excavating-type radula. These morphological and anatomical characteristics, along with their size and mobility, allow species of these groups to specialize on large and expansive macrophytes such as sea grasses, kelp, and encrusting coralline algae. Although species diversity is much higher in other groups of mollusks such as nonlimpet gastropods, it is the functional characteristics of these two groups that make them capable of consuming and even trophically specializing on the tough or limestone-imbedded cells of kelp or coralline algae, respectively.

Convergent functions are numerous among terrestrial organisms. For example, a diversity of flowering plants and their pollinators possess similar morphological and anatomical characteristics despite significant phyletic separation among the plants and the pollinators. The geometry of the flowers, such as the length and width of the floral tube, as well as the placement of nectaries are common features among the plants. The flying characteristics and mouthparts are convergent among the pollinating insects, butterflies, moths, bats, and birds. It is surprisingly easy to find functional similarities among distantly related organisms.

Groupings among Sessile Organisms

Convergent morphology and anatomy is common among sessile organisms on land and in the sea. I briefly consider terrestrial plant communities that have many of the same convergences described previously for animals. Families of cactus-like plants in the Old World (Euphorbiaceae) and New World (Cactaceae) dominate arid environments but are unrelated. Much has been written about the remarkably convergent forest and biomes that develop under similar environmental conditions (Huston, 1994). There appear to be relatively few adaptive solutions to common environmental conditions. Often, the suite of characteristics that improve ecological function under specific conditions define functional groupings.

Functional groupings among sessile organisms were studied by terrestrial ecologists, who grouped plants according to their size and the location of their growth and regenerative structures. Raunkiaer (1934) showed that particular functional groups (called “life-forms”) persisted and dominated the vegetation under similar environmental conditions. Using this scheme, Arctic regions were clearly distinguished from arid or tropical regions. Similar floras, defined at the functional group level, dominated under similar conditions in different regions even though there were often no species in common. This early focus on the size and placement of growth and regenerative structures was based on the realization that gradients in environmental stress and productivity relative to disturbances are critical to the success of specific life-forms. Plants with protected meristems and perenniating structures persisted in stressful or highly disturbed habitats. Where environmental limitations were relaxed, plant size and competitive ability were more important to the flora.

Recently, the field has become popular among marine ecologists and paleontologists who study sessile marine organisms. Again, morphological and functional convergences

Figure 5 Convergent evolution among placental (left) and marsupial (right) mammals (Reproduced from Begon M, Harper JL, and Townsend CR (1986) *Ecology, Individuals, Populations and Communities*. Sunderland, MA: Sinauer.).

are viewed more as the rule than the exception. Several growth forms have evolved convergently among widely disparate groups, such as marine algae, Cnidaria, and Bryozoa (Figure 7). Most extant and extinct species within those higher taxa can be placed within the groups illustrated in Figure 7. The growth forms represent a morphological progression. The simplest growth form is solitary and can be a single cell as is the case of a diatom or a solitary organism. This group is often composed of small organisms. The next step in a morphological progression of growth forms simply involves a linear

series of the single cells or modules, creating simple filaments. These can grow prostrate along the substrate as recumbent algal filaments or as runners or vines among sessile invertebrates. Similar morphologies growing vertically escape the benthic boundary layer. They experience greater water flow, and most of the cells of these groups are in contact with their aqueous environment. The more massive multiseriate or multiserial organisms allow three-dimensional space to be exploited. Several ecological processes, such as productivity and competition, vary predictably as sessile organisms become larger and more

Figure 6 The teeth (i.e., radulae) of herbivorous mollusk functional groups. Black teeth are heavily mineralized, making them harder than the limestone they graze (Reproduced from Steneck RS and Watling LE (1982) Feeding capabilities and limitations of herbivorous molluscs: A Functional group approach. *Mar. Biol.* 68: 299–319.).

Growth Forms	Construction & Characteristics	Examples		
		Algal	Coral	Bryozoans
	Solitary individual or Single cell (high SA/V) Small size	Microalgae Diatoms	Solitary <i>Flabellum</i> <i>Fungia</i>	
	uniserial colony or uniseriate prostrate filament	Recumbant filaments (turf) <i>Herposiphonia</i>		"Runners & Vines" <i>Pyripora</i>
	uniserial colony or uniseriate or oligoseriate erect filament	Cladophora, Sphacelaria, Polysiphonia	<i>Madrepora</i>	<i>Scruparia</i>
	Multiserial colony or multiserial, corticated erect, large size (exploits vertical space)	Corticated and Leathery macroalgae <i>Gracilaria</i> , <i>Sargassum</i> kelp (Laminariales)	Branchers <i>Pocilopora</i> , <i>Acropora</i>	<i>Cystisella</i>
	Multiserial or multiserial encrusting (Lowest SA/V), expansive but low profile (exploits horizontal space)	Crustose <i>Lithothamnion</i> <i>Petrocelis</i>	<i>Montipora</i>	<i>Stylopoma</i>

Figure 7 Growth forms of sessile marine organisms. Examples include several divisions of marine algae and Cnidaria and Bryozoa phyla. Other groups having some of the same growth forms include the extinct tabulate and rugose corals and modern sponges (Reproduced from Coates AG and Jackson JBC (1985) Morphological themes in the evolution of clonal and asexual invertebrates. In: Jackson JBC, Buss LW, and Cook RE (eds.) *Population Biology and Evolution of Clonal Organisms*, pp. 67–106. New Haven, CT: Yale Univ. Press.).

massive. With increasing mass, fewer cells directly contact the marine environment. Fewer still are in contact with the environment among the encrusting forms because half of their surface area is affixed to primary substrate. The growth forms in

Figure 7 exhibit progressively increasing size and generally decreasing surface area to volume ratio.

For benthic marine algae of all three major divisions (= phyla), the progression from single-celled microalgae to

filamentous, foliose, larger erect forms and finally to crustose algae (Figure 7) corresponds to a reduction in productivity per unit biomass (Figure 8A; Steneck and Dethier, 1994). In general, microalgae and filamentous forms with a high surface area to volume ratio are capable of the highest mass-specific productivity. This decreases progressively from filamentous forms to the more massive erect forms including kelp and is lowest among the crustose forms. Thallus longevity (Figure 8B) increases along the same continuum of growth forms. Canopy height, however, shows somewhat of a bell-shaped curve, with the tallest algal forms such as kelp and fucoid algae having intermediate levels of productivity and longevity (Figure 8C). These emergent ecological properties were shown for cold-water floras of the Atlantic and Pacific as well as for tropical floras of the Caribbean (Figure 8).

Morphologically and functionally similar organisms have evolved similar ways to overcome similar problems. For example, as organisms become more massive, fewer cells are in direct contact with the marine environment. That is, they have a plumbing problem. Sessile organisms such as plants, algae, and invertebrates evolved physiological integration or a degree of interdependence and cooperation among cells within an organism or modules within a colony. Often this involves sharing cytoplasm or photoassimilates within the organisms and among modules of a colony.

Physiologically integrated colonial organisms have an advantage over physiologically isolated acolonial organisms by sharing cytoplasm among members of the colony.

Sessile organisms can respond from a stimulus by growing at a place distant from the stimulus. Wound healing can be facilitated and mortality of the genet reduced by physiological integration. Physiological integration evolved iteratively among sessile organisms on land and in the sea. This allows land plants such as vines to colonize the inhospitable habitats of sand dunes or tree canopies by being physiologically integrated. The most abundant marine algae, the red encrusting coralline algae, are integrated and this is thought to have contributed to their ecological and evolutionary success over unintegrated or poorly integrated algae. Arguably, physiological integration in algae is essential for their morphological diversity. The least physiologically integrated group, Chlorophyta or green algae, have the lowest morphological diversity despite having the same long period of evolutionary history dating back to the Precambrian.

Physiological integration may be a prerequisite for the development of coral reef ecosystems. It evolved independently among cnidarian reef builders: the tabulate, rugose, and finally the scleractinian corals. In each case, the proportion of species with a high degree of physiological integration increased during times of significant reef-building activity. Coral reef ecosystems require high rates of coral growth to keep up or catch up with rising sea level. Reef-building corals today are physiologically plants, with endosymbiotic algae producing carbohydrates necessary for growth. Transport of photosynthetic products throughout the coral colony requires a high

Figure 8 Emergent ecological properties of benthic marine algal functional groups. (A) Mass-specific productivity of algae from southern California, the Caribbean, and Hawaii. (B) Thallus longevity of 27 species from 25 published studies. (C) Canopy heights measured in the field for dominant species in Maine, Washington, and the Caribbean. Lines envelop the maximum canopy heights recorded for each algal functional group and points represent average canopy heights per species. Error bars represent one standard deviation. Reproduced from Steneck RS and Dethier MN (1994) A functional group approach to the structure of algal-dominated communities. *Oikos* 69: 476–498.

degree of physiological integration. Without high rates of coral growth translating to high rates of reef growth, coral reef ecosystems would stand little chance of remaining in the shallow turbulent zone in which they thrive. In fact, it is likely that many coral reef ecosystems that have dominated shallow seas for much of the past 600 million years require the framework-building corals to be physiologically integrated.

Physiological integration must be functionally important to sessile organisms because it evolved independently many times. It is necessary for the similar functional groups found among the corals, algae, and bryozoans (Figure 7). Colonial integration, or the degree of interdependence and cooperation among modules within a colony, is important for all these groups because it increases colonial function. It also allows the development of nonfeeding defensive or reproductive functions within the colony or clone, and it allows greater structural integrity and morphological diversity. The important functional advantages of physiological integration may account for why it has persisted and become ubiquitous among so many unrelated sessile, colonial, and clonal organisms.

The Structure and Functioning of Natural Communities and Ecosystems

There exists a broad spectrum of ways to describe patterns. Historically, the emphasis in ecology has been on species. As Naeem (1998) pointed out, species are often viewed as being phylogenetically “singular” and likely to be “autecologically singular.” This was the basis of the important works by Hutchinson and MacArthur (1959), who stressed the uniqueness of species. That no two species can occupy the same ecological niche was the foundation of decades of studies on the structure and function of natural communities and ecosystems. Functional group approaches are different. They stress similarities among unrelated species that share critical organismal features. Convergent evolution in many cases results in phylogenetically distant organisms sharing ecological properties. The utility of using shared species characteristics for describing communities rests on the idea that in any given environment there are relatively few species attributes important to the structure and functioning of natural communities and ecosystems. These attributes are largely independent of the biodiversity of the ecosystem.

The importance of any species or group can relate to its abundance (measured as population densities, biomass, areal cover, or structural height) or its impact on other species. Whittaker (1965) argued that species’ importance should be measured by its productivity or effect on productivity. Obviously, the production of biomass must be approximately matched to its degradation or “disturbance” (*sensu* Grime, 1981). In some systems, species importance depends more on the role of disturbance (e.g., predation) than on productivity. For both disturbance and productivity, properties of the organisms and properties of the environment must be considered simultaneously and independently. Holdridge’s (1947) classic “life zone system” for classifying terrestrial vegetation considered only precipitation and temperature as driving productivity and thus

creating discrete vegetative communities and ecosystems. Others have shown how disturbances such as storms and fires additionally shape terrestrial plant communities. Although debates continue regarding the primacy of bottom-up or productivity-driven vs top-down or disturbance-driven structure of natural communities, in most systems both components are viewed as important. Therefore, the debate is largely over relative importance.

Productivity and disturbance are the two variables most often identified as environmental structuring agents of natural communities and ecosystems. Huston (1994) reviewed the work of others to develop a model that compared the frequency of disturbance (defined as patch or gap formation) as a function of “potential plant productivity.” Relative to these two axes, he showed consistent patterns in the terrestrial realm in species diversity, patch formation, dominance, and competitive ability. General models of community dominants have been advanced by Grime (1981), Southwood (1988), and Steneck and Dethier (1994) (Figure 9). Specifically, Grime (1981) suggested that, in environments with a high productivity potential (low stress) and low disturbance potential, large, canopy-forming trees will dominate the system (called a “competitive strategy”). Under conditions that favor high productivity with increasing productivity, perennial herbs and finally weedy annual herbs will come to dominate the system (called a “ruderal strategy”). Under low disturbance and low productivity potential environments, stress-resistant groups such as lichens will dominate the system (Figure 9A).

Several studies applied Grime’s (1981) model to the marine realm (Figure 9C). Strong similarities between the two realms surfaced, including that the highest biomass and largest canopy-forming organisms (trees and kelp) grow under high productivity and low disturbance potentials (Figure 9C). Furthermore, low biomass and canopy height dominated by encrusting growth forms are characteristic of stress-tolerant assemblages in both realms. A difference might occur among the organisms that dominate under conditions of chronically high levels of disturbance. Grime (1981) assumed that it is impossible to withstand such conditions and thus weedy, “ruderal strategies” would persist, whereas Steneck and Dethier (1994) argued that an additional group of organisms tolerant of such disturbances (the coralline algae) predictably dominate such systems. Although it is common to find disturbance-resistant plants under conditions of high stress in the terrestrial realm, they can be found under conditions of low stress (high productivity potential) in the marine realm. It is unclear whether this functional difference between the marine and terrestrial realms is real or perceived. Nevertheless, one value to a functional group approach is that this dialog can occur at all.

Ecosystem Diversity, Stability, and Redundancies: Examples from Coral Reefs

Much has been written on this topic, but most of the literature draws from terrestrial studies such as O’Neill *et al.* (1986); Schulze and Mooney (1994a), and Huston (1994). However, rather than reiterating these studies and their myriad examples, I will use coral reef ecosystems as examples in this

Figure 9 Generalized model of community dominants that compares Grime's (1981) model for terrestrial plants (A) with that of Steneck and Dethier (1994) for marine algae (B). (C) A synthesis of A and B. Grime's primary "strategies" or groupings of "competitive," "ruderal," and "stress tolerance" are denoted by the letters C, R, and S, respectively.

section. Coral reefs provide excellent, albeit often overlooked, examples. They are spatially discrete and smaller in vertical and horizontal structure than most of their terrestrial counterparts. Most of their functional components are readily visible (there are few below-surface functions), and major alterations and resilience can be measured in years and decades rather than centuries for observing ecosystem changes. Biogeographically, they vary widely in species diversity and thus are ideal for comparing ecosystem structure and function relative to their biodiversity.

If relatively few environmental factors can structure communities and ecosystems at the functional group level, then

what role does species diversity play? Here, I consider biodiversity and its role in the stability, structure, and functioning of coral reef ecosystems. If functional groups are composed of ecologically equivalent species, then perhaps diversity within these groups contributes to the redundancy of important functions and thus may be ecosystem insurance for stability.

Diversity and Stability

Ecosystem and community stability was once thought to correspond directly with species diversity. MacArthur (1955)

theorized that the stability of a community will increase as the number of links in its food web increases. It followed that with the loss of each species “the integrity of the biosphere will degrade in a small but significant way” (Lawton and Brown, 1994, page 255). Alternatively, species richness may be relatively unimportant as long as structuring processes controlled by primary producers, consumers, and decomposers are maintained and function well with very few species. In fact, it is now widely believed that “ecosystem processes often have considerable redundancy built into them” (Lawton and Brown, 1994, page 266). Functional groups can be composed of the redundant species that perform essential ecosystem processes.

There is good empirical evidence that diverse ecosystems are not stable. Coral reefs are among the most diverse and most productive ecosystems in the world, but they are not characteristically stable. In the Caribbean and Indo-Pacific reef coral cover, abundance and dominance suddenly changed as the result of changes in abundance of a single echinoderm species in each of the two regions. In 1983, the mass mortality of the Caribbean sea urchin, *Diadema antillarum*, caused a rapid “phase shift” that increased macroalgal biomass and contributed to the decline of live coral cover in Curacao, St. John, Jamaica, and St. Croix. In all cases, algal assemblage dominance shifted from turf algae (Figure 8A, Nos. 1–3) to macroalgae (Figure 8A, Nos. 4–6), and this caused a decline in mass-specific primary productivity. It also precipitated changes in the abundance of other herbivores. The abundance of all reef-building organisms (corals, hydroids, and coralline algae) declined sharply in shallow zones where carbonate production is normally highest.

In the Indo-Pacific, periodic, localized outbreaks of the predatory sea star *Acanthaster planci* caused coral cover declines of all species of between 85 and 94% as reviewed by Connell (1997). Other disturbances, such as storms, sedimentation, toxins, and fishing, have also been shown to cause significant reductions in coral cover. In the cases of very rapid (“acute or pulse”) mortality from sea star predation, rapid recovery at decadal timescales was observed. Other longer lasting (“chronic or press”) mortality events had slower rates of recovery. However, in the scale of years to decades these highly diverse ecosystems were demonstrably unstable.

Ecosystem resilience is sometimes considered a correlate of stability. Rapid recovery from disturbances was more commonly observed in reefs of the Indo-Pacific than in reefs of the Caribbean, where no recoveries have been documented. Reef recovery relates more to the nature and duration of the disturbances than to the biodiversity of the system. One of the best examples of recovery from collapse is in some reefs of Hawaii, although the species diversity there was as low as that found throughout the Caribbean (Table 1).

Diversity and Ecosystem Structure

The basic structure of coral reef ecosystems does not vary with biodiversity. Coral reefs throughout the Indo-Pacific, Caribbean, and at Clipperton Atoll (eastern Pacific) have similar morphological zonation of corals despite a two orders of magnitude difference in coral species richness (Table 1). Branching corals dominate shallow zones, mound-shaped forms at greater depths, and platy corals at still greater depth. At Clipperton Atoll, one of the most species-depauperate reefs in the world, Glynn and coworkers (1996) measured vertical growth rates of coral similar to those found for similar morphologies at similar depths elsewhere in the Indo-Pacific. Steneck (1988) found similar patterns of zonation, distribution, and abundance among marine algae and herbivores at the functional group level in most studied reef systems of the Indo-Pacific and Caribbean. Others showed that functional characteristics of reef fish, such as size, activity rhythms, and relative abundances among ecological and trophic categories, were similar regardless of the species richness of the fish fauna.

Diversity and Ecosystem Function

Species diversity is always low at high trophic levels. Often a single, “apex” predator is critical to the structure of some systems. However, at lower trophic levels, diversity increases, and it is at these levels (among herbivores and primary producers) that the relationship between ecosystem diversity and function is best examined at the level of functional groups.

Herbivores

Reef-dwelling herbivores have been grouped according to their grazing abilities on algal communities (Table 2). Deep grazing (i.e., carbonate scraping herbivores), parrotfishes, and certain sea urchins (e.g., *Diadema*) have the greatest impact on algal abundance. Other fishes, such as surgeonfish (acanthurids), certain damselfishes and blennies, and some gastropods, are “denuding” herbivores in that they can significantly reduce fleshy algal biomass when at sufficiently high densities. This group does not bite into limestone structures of reefs. They cannot feed on crustose corallines and have a limited ability to consume articulated algae and large leathery macroalgae. Nondenuing herbivores have little or no ability to reduce algal biomass and include territorial damselfishes and smaller herbivores, such as amphipods and polychaetes. Each of these herbivore functional groups performs distinctly different ecological roles in the ecosystem, and all were found on the species-depauperate Clipperton Atoll. The abundance of species within a functional group compensates for low diversity

Table 1 Comparison of Coral Reef biodiversity^a

Region	Coral species	Reference	Fish species	Reference
Indo-Pacific	350	Karlson and Cornell (1998)	3000	Lieske and Myers (1994)
Caribbean	50	Karlson and Cornell (1998)	750	Lieske and Myers (1994)
Hawaii	50	Hoover (1998)	680	Hoover (1993)
Clipperton (Eastern Pacific)	7	Glynn <i>et al.</i> (1996)	101	Robertson and Allen (1996)

^aSpecies richness of scleractinian corals and reef fishes.

Table 2 Functional groups of herbivores common on Coral Reefs^a

Functional group	Specific group	Common reef-dwelling genera
Scraping	Parrotfish	<i>Scarus</i> , <i>Sparisoma</i>
	Sea urchins	<i>Diadema</i> , <i>Echinometra</i> , <i>Echinothrix</i> , <i>Lytechinus</i>
Denuding	Limpets, chitons	<i>Acmaea</i> , <i>Acanthopleura</i> , <i>Acanthochitona</i> , <i>Choneplax</i>
	Surgeonfish, signids, Few pomacentrids	<i>Acanthurus</i> , <i>Naso</i> , <i>Zebbrasoma</i> , <i>Siganus</i>
	Blennies, kyphosids	<i>Microspathodon</i>
Nondenuding	Damselfish	<i>Ophioblennius</i>
	Snails (excluding limpets)	<i>Stegastes</i> , <i>Pomacentrus</i> , <i>Eupomacentrus</i>
	Amphipods	<i>Nerita</i> , <i>Cittarium</i> , <i>Tectarius</i> , <i>Astraea</i> , <i>Fissurella</i>
	Polychaetes	<i>Amphithoe</i> , tanaids Eunicids, syllids.

^aBased on more than 30 published studies (after [Steneck, 1988](#)).

within the group. For example, high rates of scraping herbivory were evident at Clipperton, but all such grazing resulted from a single parrotfish species and several species of diademid urchins. The abundant crustose coralline algae, which are often found on reefs experiencing high rates of grazing, were covered with graze marks from scraping herbivores ([Table 2](#)). High rates of grazing, low fleshy algal biomass, and a high abundance of both corals and coralline algae are characteristics of relatively pristine reefs. That these conditions were found in as species depauperate a system as Clipperton Atoll suggests that ecological roles of functional groups can be independent of species diversity.

Primary Producers

Primary productivity is a significant component of ecosystem functioning. A functional approach to ecosystem study often “implies that energy flow and nutrient cycling are somehow more important or more fundamental than the biotic entities performing the function” ([O’Neill et al., 1986](#), page 10). Although there may be no species in common, the same functional groups of marine algae are found on virtually all coral reefs. Since the productive components of reefs (algal turfs, corals, and macroalgae) all occur in approximately similar proportions, ecosystem-level productivity is fairly consistent. Thus, Caribbean reefs with only a fraction of the species richness of the western Indo-Pacific reefs have similar rates of gross primary productivity. Other factors, such as the geological history of the reefs and their proximity to land, have much greater impacts on ecosystem production than do reef biogeography or species diversity per se. Note that these patterns of consistent rates of productivity among unstressed reefs do not negate the well-known pattern of low diversity in stressed habitats.

Equivalent Species and Ecosystem Redundancy

Species within a function group, by definition, are ecologically equivalent and as such provide a degree of redundancy to the ecosystem. One test of functionally equivalent species is if their abundance compensates as other species within the functional group change. Morphological and functional equivalency is evident within turf algae on coral reefs. Many genera of different divisions look similar. They often grow as

prostrate branching filaments, with relatively few laterally divided “pericentral” cells. Many species among these genera ([Figure 10A](#)) have about the same high rates of productivity ([Figure 8A](#)) and they respond similarly to injuries. In the fore reef of St. Croix, dominance and abundance of algal species changed dramatically from season to season at the species level but very little at the functional group level ([Figure 10B](#)). That algal community biomass remained relatively constant throughout the year, as species composition fluctuated greatly, suggests that species within functional groups compensate for species fluctuations.

It is necessary to sort out functionally important changes from redundant species “noise.” On the fore reef of St. Croix ([Figure 10](#)), seasonal changes among species were so great that it was impossible to describe it as having a characteristic dominant species. However, at the functional group level, a clear pattern of filamentous and microalgal (i.e., turf algal assemblage) dominance was evident. These algae readily coexist with reef-building corals. In contrast, macroalgae comprised a minor component of this flora and appeared only in winter and spring. The functional distinction between macroalgae and the dominant micro- and filamentous algae is important. The algal turf assemblage was composed of species which have the highest mass-specific productivity (i.e., algal functional group Nos. 1 and 2 in [Figure 8A](#)). Trophically, these algal communities support very high levels of grazing. The herbivorous fish and urchins cannot distinguish species within the diverse algal turfs, and thus no species preferences are possible and there are no known chemical deterrents within this assemblage. Any of the filamentous algal species could have gone locally extinct (many did seasonally) without functionally changing the system. As such, many of the species within these functional groups are redundant.

Compensation is also evident among ecologically equivalent functional groups of herbivores. In shallow reef zones, the grazing effects from parrotfish and sea urchins are functionally similar ([Table 2](#)). They are both capable of grazing deeply into limestone substrates and can control the structure of algal communities on reefs. Several studies have reported that deep-grazing sea urchins and fish compete and show compensatory changes in relative abundance when one group is excluded or removed. [Hay \(1984\)](#) found that reefs where fishing was important were dominated by sea urchin grazing, whereas with little fishing pressure reefs were dominated by herbivorous

Figure 10 Seasonal stability of the 10 most abundant algal species (A) and functional groups (B) on a fore reef of St. Croix. Differences in the total percentage represented among seasons for species (A) and functional groups (B) resulted from the different proportions of unidentifiable components when samples were analyzed at species vs functional group levels. Functional group numbers correspond to the ones plotted in Figure 8. Functional groups were further combined into common tropical algal assemblages (i.e., crustose algae, turf algae, and macroalgae). Reproduced from Steneck RS and Dethier MN (1994) A functional group approach to the structure of algal-dominated communities. *Oikos* 69: 476–498.

fishes (e.g., scraping and denuding fishes in Table 2). Subsequent studies at several locations in the Caribbean and Indian Ocean found that when urchins were removed experimentally or naturally due to a disease-induced mass mortality, fish abundance and grazing increased as urchin abundance declined. In regions of the Caribbean traditionally having a relatively low abundance of *Diadema antillarum*, another urchin, *Echinometra viridis*, was abundant and filled *Diadema*'s functional role.

Ecosystem Insurance

Species diversity within functional groups buffers ecosystems against species loss, but often there is "a threshold of change that will overwhelm the damping effect of biodiversity, with an associated break point of ecosystem function to quite different levels" (Schulze and Mooney, 1994b, page 501). Unfished reefs contain high within-functional group diversity at several levels. There are several species of large

carnivores (e.g., groupers and snappers), denuding herbivores (e.g., surgeonfish), and scraping herbivores (e.g., parrotfish) that, when abundant on reefs, control the reef's overall structure and functioning. Fishing affects reefs by first removing large-bodied carnivores and then herbivores. Reefs under particularly intense fishing, such as in Jamaica, are left with few or very small fishes. Compensatory population increases in the sea urchin *D. antillarum* probably occurred (Figure 11), causing it to become hyper-abundant and the prime grazer of the reefs of Jamaica and elsewhere in the Caribbean. Levitan (1992) showed that *Diadema*'s increasing role as a grazer throughout the Caribbean corresponded with increasing human populations and associated fishing pressure. On many Caribbean reefs this herbivore became the primary grazer within the functional group of scraping herbivores (Table 2). Arguably, the diversity within this functional group had decreased to one species (Figure 11). When *D. antillarum* suffered a mass mortality in 1983, the "break point" had been exceeded and reef ecosystems throughout the Caribbean collapsed.

Figure 11 Temporal changes in Jamaica's coral reef ecosystem in coral to macroalgal abundance relative to herbivorous fish and sea urchin, *Diadema antillarum*. After herbivorous fishes were extirpated by overfishing, grazing remained high due to compensatory increases in *Diadema* abundance. The reef ecosystem collapsed soon after the mass mortality of the urchin (see text) (Adapted from Done TJ (1995) Ecological criteria for evaluating coral reefs and their implications for managers and researchers. *Coral Reefs* 14: 183–192.).

Keystone Species to Functional Groups: Some Species Are More Equal Than Others

Some species have a disproportionately great impact on ecosystems. Hurlbert (1997) noted, "The general functional importance of a species (can be) defined as the sum, over all species, of the changes (sign ignored) in productivity which would occur on removal of the particular species from the (system)" (page 369). Most communities and ecosystems are dominated by a few species that are both abundant and important to that system (Figure 12). The few tree species that dominate given forests, corals that dominate zones of reefs, and specific grasses that comprise specific prairies need not be functionally grouped to be easily understood. The loss of community or ecosystem dominants has a large impact on natural systems. Diseases can eliminate dominant organism with impacts registering throughout the system. American chestnut blight eliminated chestnuts from forests in eastern North America. White-band disease killed most of the dominant elkhorn and staghorn corals and a pathogen caused the *Diadema* decline in shallow Caribbean reefs. Rinderpest decimated wildebeest populations in Africa, and paramoebae caused a mass mortality of the green sea urchin in Nova Scotia. Each of these dominant or "foundation" (*sensu* Dayton, 1972) species underwent a radical decrease in abundance, causing their respective ecosystems to change. In these cases, the functional importance of these species is unquestioned.

Keystone species have been redefined by Paine (1995) and Power *et al.* (1996) to include organisms that are functionally important but in relatively low abundance in the system. Pathogens aside, this limits keystone species to apex predators. Classic keystone predators such as sea otters or the predatory sea star, *Pisaster*, are the only species in their system and thus define their ecological function. However, many systems do not

Figure 12 Functional importance and abundance of species. The relatively low diversity of dominant/foundation and keystone species as well as the relatively low ecosystem importance of rare organisms make these groups poorer candidates for functional groupings (Modified from Hurlbert SH (1997) Functional importance vs keystoneity: Reformulating some questions in theoretical biocenology. *Austr. J. Ecol.* 22: 369–382.).

have an obvious apex predator. In contrast with the marine systems of the eastern North Pacific in which sea otters and *Pisaster* roam, the western North Atlantic has no single apex predator. Top coastal predators include cod, haddock, hake, and wolffish. When all these top predators were extirpated simultaneously by overfishing, the system changed. Therefore, whether there is a single apex predator (i.e., a keystone species) or a functional group filling the same role matters little. In other words, the ecological function can be carried out by a single species or by a suite of species, but the ecosystem will not change unless the ecological function changes significantly. In the end, the ecological function, independent of the diversity, may be most important to the structure of ecosystems.

The utility of functional groupings relates directly to the diversity of the system, community, or trophic level of interest. It will be most useful in sorting out the functional importance in diverse systems among moderate to very abundant organisms (i.e., the center of Figure 12). Functional groups lose their utility among the rare, dominant, and keystone species (i.e., the periphery of Figure 12). Not only is species diversity low at high trophic levels but also it is characteristically low in certain stressed habitats, such as deserts, the rocky intertidal zone, estuaries, and high-altitude or high-latitude habitats. Functional group utility is likely to be greatest in diverse systems in which many species perform similar ecological functions.

Conclusions

Despite Earth's remarkable biodiversity, the range of functionally different organisms is surprisingly low. Phyletic constraints on evolution relative to biomechanical limits of what works in nature limit the number of functional groups in any system to a management level. In highly diverse ecosystems there are many redundant species within functional groups. These redundancies provide a buffer against ecosystem collapse should individual species within the group become rare or extinct. Ultimately, functional groups may provide a low-resolution tool for accurately predicting ecosystem change. Research to improve how we identify and define functional groups is likely to increase our understanding of the structure and functioning of natural communities and ecosystems.

Glossary

Diversity-productivity hypothesis The proposal that greater diversity would lead, on average, to greater total biomass or productivity.

Diversity-stability hypothesis The proposal that ecosystems containing more species would be more stable.

Ecosystem composition The list of species or functional groups that are present in a given ecosystem.

Ecosystem functioning The rate, level, or temporal dynamics of one or more ecosystem processes such as primary production, total plant biomass, or nutrient gain, loss, or concentration.

Functional diversity The range and value of those species and organismal traits that influence ecosystem functioning.

Functional group A set of species that have similar traits and that thus are likely to be similar in their effects on ecosystem functioning.

Niche differentiation Differences in the morphology, physiology, or behavior of species that can influence their abundances, dynamics, and interactions with other species, including the ability of various competing species to coexist.

Sampling effect The hypothesis that diversity might influence an ecosystem process because of the greater chance that a given species trait would be present at higher diversity, and the effect of its presence on ecosystem functioning.

Measurement of Functional Diversity

Because of the large number of traits that each species possesses, the large number of different species that exist in most habitats, and the incomplete knowledge of which species traits influence various ecosystem processes, there is, as yet, no simple way to measure functional diversity. Rather, items that are more easily measured than functional diversity are used as indices or correlates of functional diversity. The most common of these indices is the number of species present in a habitat, which is called the species richness or species number of the habitat. All else being equal, habitats with greater species richness should also have greater functional diversity. This occurs because species differ in their traits. Sites that contain more species should thus also contain, on average, a greater range of species traits, which is greater functional diversity. Species diversity indices, such as the Shannon diversity index, are similarly used as indirect measures of functional diversity. Another commonly used index of functional diversity is the number of different functional groups (defined later) that exist within a given community or ecosystem. This is also called functional group diversity. Assuming that organisms can be categorized as belonging to groups that differ in traits relevant to ecosystem functioning, greater functional group diversity should correlate with greater functional diversity. However, variations among species within a given group could also contribute to functional diversity. Observational, experimental, and theoretical studies indicate that functional diversity, as measured by any of these three means, is one of several important factors that determine ecosystem functioning. Because there is, as yet, no clear way to measure functional diversity, one or more of these three indices will be used as a proxy for functional diversity in this chapter.

Before reviewing the research linking functional diversity to ecosystem processes, which is the focus of the remainder of this chapter, it is important to introduce and define some terms.

Explanation of Concepts and Terminology

Functioning

As they are used by ecologists, the words *function*, *functional*, and *functioning* are not meant to imply that an ecosystem process has any underlying goal or purpose. Indeed, to try to minimize any such implications, it has become standard practice to refer to “ecosystem functioning” or “ecosystem process” rather than the “function of an ecosystem.” The latter might be misinterpreted as meaning that an ecosystem exists to perform a given function, which is inconsistent with our knowledge of the process of evolution. Rather, functioning refers solely to the way in which an ecosystem operates.

Ecosystem Processes

Ecologists study many different aspects of the functioning of communities and ecosystems. The three most frequently considered ecosystem processes are productivity, stability, and resource dynamics. Productivity refers to the rate of production of biomass within a given trophic level. The production of plant biomass is called primary production, the production of biomass of herbivores is called secondary production, and that of predators is called tertiary production. Stability has a wide range of definitions, including the degree to which an item is resistant to change when experiencing a

single perturbation, the degree to which an item fluctuates in response to an ongoing suite of small-scale perturbations, and the dynamics of return to its prior state after a single perturbation. Stability can be measured at the level of populations, communities, or ecosystems. The resource dynamics of an ecosystem are measured by the rates of supply and loss of limiting nutrients, by the efficiency with which organisms use limiting resources, and by the proportion of limiting resources that the organisms living in an ecosystem are able to capture.

Functional Groups

Each species has a large number of morphological, physiological, and behavioral traits, many of which might influence the abundance of species and ecosystem functioning. One way to deal with such complexity has been to identify traits that seem more likely to influence ecosystem processes. Chapin *et al.* (1997) suggested that the species traits with the greatest effects on ecosystem functioning were those that (a) controlled the acquisition, use, and availability of limiting resources; (b) modified the feeding structure of food webs; and (c) affected the occurrence and magnitude of disturbances. Such traits can be used to classify organisms into different functional groups. For instance, species can be divided, first, into functional groups based on their position in a food web: photosynthetic plants, herbivores, predators, parasites, parasitoids, decomposers, and so on. Organisms within each of these groups can be further subdivided based on their acquisition and use of their limiting resources. For grassland plants, for instance, this might be based on the time, within the growing season, when each plant was maximally active (cool-season versus warm-season plants), and on its carbon (C-3 or C-4 photosynthetic pathway) and nitrogen physiology (high nitrogen use efficiency, low nitrogen use efficiency, ability to fix atmospheric nitrogen). Such considerations might lead, for instance, to the classification of grassland plants into six functional groups: C-3 grasses, C-4 grasses, C-3 forbs, C-4 forbs, legumes, and woody plants. The assumption inherent in making such a classification is that species within a class are highly similar, and those in different functional groups differ markedly from one another.

Diversity versus Composition

It has long been recognized that the functioning of an ecosystem depends on which species the ecosystem contains (i.e., on its species composition). Interest in species diversity as an alternative or additional explanation for ecosystem functioning means that it is necessary to define species diversity, especially functional diversity, in a way that distinguishes diversity from species composition. This requires a definition that is more restricted than that traditionally used. In particular, effects should be attributed to diversity only once there has been simultaneous control for effects of composition, and effects should be attributed to composition only once there has been simultaneous control for effects of diversity. To achieve this in an experimental, theoretical, or observational study, it is necessary (a) to hold composition constant via

randomization (numerous communities with randomly-chosen compositions) while changing diversity, (b) to hold diversity constant while changing composition, (c) to simultaneously vary both in an appropriately randomized and replicated design, or (d) to control for each statistically, such as via multiple regression, which is most appropriate for observational studies.

Early Work on Functional Diversity and Ecosystem Processes

Effects of diversity on ecosystem processes were first recognized by Darwin in *The Origin of Species*. Darwin noted that it was well-known that increased plant diversity led to greater primary productivity in pastures. The British ecologist, Charles Elton, hypothesized in his 1958 book titled *The Ecology of Invasion by Animals and Plants* that diversity would impact many aspects of ecosystem functioning. In particular, he suggested that greater diversity would lead to greater ecosystem stability, an idea that was further developed by the leading ecologists of that era, including Robert MacArthur, Gene Odum, and Ramon Margalef. Elton also suggested that greater diversity would decrease the susceptibility of an ecosystem to invasion by other species and would decrease the incidence of outbreaks by diseases and pests.

Elton's diversity-stability hypothesis was called into question, though, by the mathematical theory of May (1972), which predicted that the linear stability of communities of competing species would, in general, decrease as the diversity of the communities increased. The general consensus reached after publication of May's book was that other factors were likely to be more important than diversity as determinants of ecosystem processes. This view led ecologists to focus more of their attention on other issues, with much of that effort dedicated to better understanding the mechanisms of species interactions and the effects of species composition on ecosystem processes.

Recent explorations of the potential effects of diversity on ecosystem processes were inspired, to a great extent, by the publication of *Biodiversity and Ecosystem Functioning* (Schulze and Mooney, 1993). In a chapter in that book, Vitousek and Hooper hypothesized that many ecosystem processes, like primary productivity, should increase as diversity increased, and they stressed that the most important component of diversity might be functional group diversity. Agricultural studies were reviewed in a chapter by Swift and Anderson, who noted that mixed crops, especially those containing a legume and a grass, were often more productive than either crop species growing alone, supporting the diversity-productivity hypothesis. A chapter by McNaughton reviewed and evaluated a large number of observational and small-scale experimental studies in which stability was greater for ecosystems containing more species and highlighted data supporting Darwin's diversity-productivity hypothesis. These and other contributions in this book set the stage for a burst of work that has included development of additional mathematical theories, field and laboratory experiments, and observational studies.

Functional Diversity, Productivity, and Nutrient Dynamics

Theory and Concepts

The potential effects of functional diversity on productivity have been described by two qualitatively different models, reviewed in Tilman (1999). The first is the sampling effect model, simultaneously proposed in 1997 by three different authors (L. Aarssen; M. Huston; and D. Tilman, C. Lehman, and K. Thomson). The sampling effect model hypothesizes that species differ in their competitive abilities, and that species that are better competitors are also more productive. Given these assumptions, communities that have greater diversity should, on average, be more productive because they are more likely to contain one or more species that are more productive.

A formal mathematical treatment of the sampling effect, provides some deeper insight into the way that functional diversity can impact ecosystem processes. For this treatment, let R^* be the level to which a limiting resource is reduced by a species when growing alone. As shown both theoretically and in numerous competition experiments (Grover 1997), the best competitor would be the species with the lowest R^* . The R^* value of the species can be used to rank them from good to poor competitive ability (i.e., from the lowest to the highest R^* value). Assume that the species composition of a community is determined by random draws (sampling) from the infinite pool of species with all possible R^* values between a minimum ($R_{\min}^*$) and maximum ($R_{\max}^*$). On average, the functional diversity of a community would depend on the number of species drawn, N , which is the initial diversity. The number of species in a community, N , is a good measure of functional diversity in this model because the range in the values of the relevant species trait (R^*) is higher in communities containing more species. These assumptions of sampling effect yield a simple equation that relates the long-term average biomass of a plant community, $B_{(N)}$, to its original plant species diversity, N :

$$B_{(N)} = aQ \left(S - \left(R_{\min}^* + \frac{R_{\max}^* - R_{\min}^*}{N + 1} \right) \right) \quad (1)$$

Here a is the rate of resource mineralization, Q the coefficient of resource conversion into biomass, and S is the rate of resource supply in the habitat.

The sampling effect model predicts that total community biomass, a measure of primary productivity, increases with plant diversity, as shown in Figure 1a. The trend predicted is one in which added diversity leads to large increases in productivity when diversity is low, but has progressively smaller impacts when diversity is higher. This simple model demonstrates that the magnitude of the effect of functional diversity, as measured by N , on ecosystem functioning depends on the range of interspecific differences in the species pool—that is, on the term $(R_{\max}^* - R_{\min}^*)$ in Equation 1. This gives basis to the intuitive concept that diversity effects ecosystem processes because ecosystems with greater diversity have a greater range in those species traits that influence functioning.

The sampling effect model also predicts that the average quantity of unconsumed resource should decrease as diversity increases (Figure 1b). Indeed, in the sampling effect model, the increased biomass at higher diversity is caused solely by the more complete utilization of the limiting resource that occurs, on average, at higher diversity.

The model also illustrates the importance of species composition. Each point in the two graphs of Figure 1 represents the response of a community with a different randomly determined species composition. Thus, the variability among plots with the same diversity measures the impact of composition, and the variability among diversity levels represents the impact of diversity. Both diversity and composition are strong determinants of productivity and resource levels in the sampling effect model.

The other major type of models that have been proposed to relate productivity to diversity are niche differentiation models. In essence, such models assume that a habitat is spatially or temporally heterogeneous, that species differ in the traits that determine their response to this heterogeneity, and that each species is a superior competitor, and thus is more productive, for some subset of the heterogeneous habitat conditions. These assumptions can allow a large number of species to coexist and assure that ecosystem productivity increases, on average, as diversity increases. For instance, two factors, such as soil pH and temperature, might limit plant abundance. Each species could have some combination of these factors at which it performed best. Such niche differentiation would mean that each species did best in a part of the habitat, but that no species could fully exploit the entire range of conditions.

The essence of such niche models can be captured by making the simple assumptions that each species has a circular area of radius r in which it can live and be a good competitor (Figure 2a), that all species attain comparable abundances per unit habitat occupied, and that competition similarly reduces abundances of all overlapping species. If the values for one limiting factor range from 0 to a and the other from 0 to b , where a and b measure habitat heterogeneity for factors 1 and 2, and if species are drawn at random from all those that could live at some point in the habitat, then total community biomass (i.e., the proportion of environmental conditions “covered” by one or more species) would be

$$B_{(N)} = 1 - \left(1 - \frac{\pi}{ab + 2(a + b) + \pi} \right)^N \quad (2)$$

here N is species diversity. $B_{(N)}$ is an increasing function of species diversity (Figure 2b). The amount of unused habitat decreases as diversity increases, much as the concentration of unutilized resource was decreased for the sampling effect model. As for the sampling effect model, the variance within a given level of diversity is caused by differences in species composition, and differences between diversity levels is caused by diversity.

In addition, the niche model predicts that greater habitat heterogeneity (i.e., greater values of a and b) requires greater diversity in order to achieve a given level of productivity. In general, heterogeneity should increase with habitat size, leading to the prediction that greater biodiversity is required

Figure 1 (A) The sampling effect model predicts that productivity should be greater at greater functional diversity, here measured by the number of species present. The variation within a given level of species richness is caused by different species compositions. (B) Productivity is higher in plots with greater functional diversity because of greater capture of the limiting resource. The concentration of unutilized resource is predicted to decline as diversity increases.

to attain a given level of productivity in larger habitats. For instance, for small, relatively homogeneous habitats ($a=b=1$), only six species are needed to attain 95% of maximal productivity. However for spatially heterogeneous habitats ($a=b=10$), a diversity of 135 plant species is needed to achieve this level.

A comparison of the sampling effect model with the niche differentiation model reveals a major difference in the expected pattern of the dependence of productivity on diversity. For the sampling effect model, there are no higher diversity plots that are more productive than the most productive monoculture. In contrast, for the niche model, there are

Figure 2 (A) A graphical illustration of a niche differentiation model. Here each circle represents the range of environmental conditions in which a given species can live, and the full rectangle shows the range of environmental conditions that occur in a given habitat. This model and similar niche differentiation models predict that productivity should be an increasing function of diversity. (B) The predicted effects of diversity on productivity for the model illustrated in part (A).

two-species plots that are more productive than the most productive monoculture, three-species plots that are better than the best two-species plot, and so on. For ecosystems that meet the assumptions of the sampling effect model, which

might occur for highly productive agricultural fields, there might be situations in which judicious choice of the right species and variety could lead to as great productivity from a monoculture as would be possible for a highly diverse mixture

of species. In contrast, for habitats with spatial or temporal heterogeneity, which should occur for almost all natural ecosystems and for all but the most intensively managed ecosystems, niche differentiation models are more likely to hold. In such cases, increased diversity is expected to lead to greater productivity and to more complete use of limiting resources.

Although these models, and the models of Michel Loreau, have predicted that greater diversity can lead to greater ecosystem productivity, this need not always be the case. For instance, if the assumptions of the sampling effect model were modified to have progressively better competitors be progressively less productive, productivity would be a decreasing function of diversity. This suggests a more general principle: if species differ in their competitive abilities, and if higher competitive ability is correlated with some other traits, then these traits will, on average, be better represented in more diverse communities, thus biasing the functioning of these communities in the direction determined by these correlated traits.

Experimental Studies

Darwin suggested that it was common knowledge among farmers that a greater diversity of pasture plants would lead to a greater production of herbage in pastures. In his 1993 chapter, McNaughton cited this and presented more recent examples in which greater plant diversity led to greater productivity, as did Swift and Anderson. Indeed, earlier work reviewed in Harper's 1977 book showed that pairs of coexisting species often yield more than either species did when living by itself. As reviewed in the 1993 chapter by Vitousek and Hooper, some of the first evidence linking higher plant diversity to greater retention of soil nutrients came from a field experiment in Costa Rica by Ewel as collaborators. They found that communities planted to many tropical species generally retained more soil fertility than those planted to monocultures.

The first published direct test of the diversity-productivity hypothesis came from a greenhouse experiment by Naeem *et al.* (1995). By growing various randomly chosen combinations of 16 plant species 1, 2, 4, 8, or 16 at a time in a greenhouse, they found that community biomass was greater at higher plant diversity (Figure 3a). This team performed another experiment in a series of growth chambers and also had results suggesting that greater diversity leads to higher productivity (Naeem *et al.*, 1994). Next came results from a large-scale field experiment begun in Minnesota in 1993 (Figure 4). Its 147 plots, each 3 m × 3 m, were planted to contain 1, 2, 4, 6, 8, 12, or 24 plant species randomly and independently chosen from a set of 24 prairie-grassland species (reviewed in Tilman, 1999). It found highly significant effects of plant diversity on both productivity (Figure 3b) and on the soil concentration of the limiting resource, nitrate (Figure 3c). By the fifth year of this experiment, its results supported niche differentiation models more than the sampling effect model as the major cause of the effects of diversity on the measured ecosystem processes. Indeed, the most productive plot in 1998 was a 24-species plot that had 65% greater total biomass than the most productive monoculture. A second experiment, adjacent to this Minnesota experiment (reviewed by Tilman, 1999), controlled for both species diversity and functional group diversity (Figure 5). Its results

Figure 3 (A) The observed effect of plant diversity on the productivity of plant communities in the greenhouse experiment of Naeem and collaborators. (B) Effects of diversity on productivity for the Minnesota field experiment in which grassland diversity was experimentally controlled in 147 plots. (C) Effects of diversity on the concentration of unutilized soil nitrate for the Minnesota experiment.

were similar to those of the first experiment and showed highly significant effects of species diversity, functional group diversity, and functional group composition on primary productivity and nutrient dynamics. In both of the Minnesota grassland diversity experiments, the vast majority of species coexisted in all plots to which they had been added, further supporting niche differentiation models.

Figure 4 The smaller of the Minnesota biodiversity experiments, shown here, has demonstrated that plant diversity has a strong effect on ecosystem productivity and nutrient dynamics. The experiment has 147 plots, each being $3\text{ m} \times 3\text{ m}$ (about 10 feet by 10 feet) in size.

Figure 5 The larger of the Minnesota biodiversity experiments uses about 270 of the 342 plots shown. It has shown strong effects of plant species richness, plant functional group richness, and plant functional group composition on ecosystem processes. Each plot is $13\text{ m} \times 13\text{ m}$ (about 40 feet by 40 feet).

Knops *et al.* (2000) recorded the number of non-planted species that invaded the Minnesota diversity experiment plots, and their biomass at the time when they were removed from the plots. They found that significantly fewer species invaded higher diversity plots and that the total biomass of invading species was lower in higher diversity plots. Further analyses suggested that the effect of diversity on invasions was caused by the lower levels of soil nitrate in higher diversity plots. This provides one simple mechanism whereby diversity may influence the extent to which an ecosystem is invaded by other species and suggests that levels of unconsumed limiting

resources may, in general, be an important determinant of the success of an invading species.

For native, undisturbed grasslands close to the two Minnesota biodiversity experiments, plant abundances were greater and soil nitrate was lower in more diverse plots (see Tilman, 1999), which is consistent with the experimental results and with the predictions of theory. However, correlational patterns must be interpreted carefully because they could be confounded by other correlated variables. Michel Loreau used a model that linked environmental factors, biodiversity, and ecosystem functioning to explore this point. The

model illustrated that correlational field data could be misinterpreted easily because of a confusion of cause-and-effect relationships. Just such issues cloud the interpretation of the possible effects of island diversity on ecosystem processes for a study of 50 Swedish islands. In an intriguing study that showed links between island size and the frequency of wild-fire, David Wardle and collaborators found that a suite of ecosystem traits were correlated with both island size and plant diversity. However, it is unclear if diversity caused the observed differences in ecosystem processes or if both these processes and diversity were controlled by fire frequency.

Hooper and Vitousek (1998) performed a field experiment, planted in 1992, in which they controlled plant functional group diversity and composition using plants common to California grasslands. After a year of growth, they found that functional group composition had a much greater effect on plant community biomass than functional group diversity, but that the utilization of soil nutrients increased significantly as diversity increased.

In a 4-month greenhouse experiment, Symstad *et al.* (1998) found that total plant biomass was significantly higher at higher diversity and that most of this effect was attributable to the presence of legumes. They also determined the effects of the deletion of individual species on total biomass and found that the strength and direction of these effects depended on which species were present and which was deleted.

In an experiment that was replicated at eight different sites across Europe, ranging from Scotland and Ireland to Portugal and Greece, Hector *et al.* (1999) found that greater plant diversity led to greater primary productivity. An important finding of this unique experiment was that the quantitative effect of diversity on primary productivity was the same across all eight sites. In combination with the other field and laboratory experiments, the European experiment suggests that there is a general, repeatable effect of grassland diversity on primary productivity.

In total, these studies show that plant productivity is greater at greater diversity and that this also corresponds with greater utilization of limiting soil resources. In general, short-term experiments showed weaker effects of diversity on productivity and soil nutrients than longer-term experiments. This is expected because diversity should impact ecosystem processes via changes in plant abundances mediated by competition, and such interactions can require several years to occur. Further work is needed on other trophic levels and in other communities to determine the extent to which the patterns observed to date apply to other trophic levels (e.g., herbivores, predators) or to other communities (e.g., marine fisheries, forest ecosystems, coral reefs).

Functional Diversity and Stability

Theory and Concepts

A large number of authors, including Charles Elton, Robert May, Stuart Pimm, and Sam McNaughton have contributed considerable insights into the effects of diversity on stability. May (1972), for instance, showed that the abundances of individual species become progressively less stable as the

diversity of the community in which they live increases. Several recent papers have explored the effects of diversity on the stability of communities of competing species (Doak *et al.*, 1998; Ives *et al.*, 1999; Tilman, 1999). The first two of these papers showed that the temporal variability of an ecosystem process, such as ecosystem productivity, is expected to be lower when the ecosystems contain more species. This can occur for the same reason that a portfolio composed of many different types of stock tends to be more stable than one containing stock of a single company. An additional factor that can cause ecosystem functioning to be more stable for more diverse ecosystems is competition. When some disturbance harms one species, the species with which it interacts experience less competition. This allows these competitors to increase in abundance. Their greater abundance partially compensates for the decreased abundance of the first species, thus stabilizing the functioning of the ecosystem. Ives *et al.* (1999) showed that increased diversity only led to increased stability when the species differed in their responses to habitat fluctuations and disturbances. Because such differences are a direct measure of functional diversity, the work of Ives *et al.* (1999) showed that increases in functional diversity lead to greater stability. For a thorough treatment of theory relating diversity and stability, see "Stability, Concept of."

Experimental and Observational Studies

The evidence that led Elton to propose the diversity-stability hypothesis was anecdotal. In his 1993 chapter, and in earlier papers, McNaughton defended the diversity-stability hypothesis by citing several observations and experiments in which greater diversity was associated with greater stability. A variety of other studies, summarized in Tilman (1999), also have found effects of diversity on stability. For instance, a study by Frank and McNaughton of eight grassland sites within Yellowstone National Park found that those with greater plant species diversity had smaller shifts in plant community compositions during a severe drought. Two British ecologists, Taylor and Woiwod, performed a long-term project in which they monitored the abundances of hundreds of insect species at a large number of sites. The data they collected provide evidence that supports the hypothesis that more diverse insect communities should be more stable. The greater stability is expected because of the statistical averaging (or portfolio) effect pointed out by Doak *et al.* (1998). Specifically, because the temporal variances in the abundances of individual species in this community scales as their abundance to a power of about 1.6, the portfolio effect should cause more diverse insect communities to have lower temporal variability.

Several authors have found that greater oak tree diversity stabilizes the population density of an animal, the acorn woodpecker, that feeds on the seeds of the trees (see Koenig and Haydock, 1999). Acorn woodpeckers are highly dependent on acorns as a source of food, but oaks produce acorns as a mast seed crop. Masting means that there is great year-to-year variability in the rate of acorn production. There is a striking decrease in the year-to-year variability of acorn woodpecker abundances for woodpeckers living in habitats containing a greater diversity of oaks. Thus, greater oak diversity led to more stable acorn woodpecker populations.

Figure 6 The resistance of Minnesota grassland ecosystems to drought was highly dependent on their plant biodiversity. Ecosystems containing a large number of plant species had their productivity fall to about half of its predrought levels during a severe drought, but those containing only one or two plant species had it fall to about 1/8 to 1/12 of the predrought level.

Moreover, acorn woodpecker densities were much lower for areas with a single oak species than for those with several.

A long-term experiment in Minnesota provides additional evidence suggesting that greater plant diversity leads to greater stability (reviewed in [Tilman, 1999](#)). In a series of 207 plots annually monitored from 1982 to 1999, total plant community biomass was found to be more stable in plots containing more species. Both in response to a major disturbance, a severe drought ([Figure 6](#)), and in response to normal year-to-year variation in climate ([Tilman, 1999](#)), plots with greater diversity had lower year-to-year variability in their total plant biomass. In particular, the severe drought caused plant biomass to fall to half of its predrought level in plots with about 15 or more species, but caused it to fall to 1/8 to 1/12 of its predrought levels in plots containing one or two plant species ([Figure 6](#)). Similarly, year-to-year variation in total biomass fluctuated about twice as much in low diversity as in high diversity plots ([Tilman, 1999](#)). Although total community biomass was more stable at higher diversity, analyses of the stability of individual species showed that these declined slightly but detectably, at higher diversity. Thus, diversity stabilized total community biomass at the same time that it destabilized the abundances of individual plant species. Plant diversity and composition were confounded in this experiment because both changed in response to nitrogen addition. Multiple regression, used to control for this confounding, found highly significant effects of diversity on stability for both cases. These analyses also showed that species composition and functional group composition also had significant effects on stability.

[McGrady-Steed, Harris, and Morin \(1997\)](#) found, in a laboratory study of the effects of diversity in microbial communities, that the temporal variability was significantly

smaller at higher diversity. Indeed, a four-fold increase in diversity led to about a three-fold decrease in the temporal variability of whole-community net respiration, a measure of ecosystem activity. The rate of microbial decomposition of particulate organic matter also increased with diversity in this study. Finally, they found that greater diversity led to lower susceptibility to invasion by another species, but that invader success was highly dependent on community composition. [Naeem and Li \(1997\)](#) similarly found that greater diversity led to greater reliability, which was measured as the lower variability in total community biomass among communities of identical diversity. This effect was also apparent in the greenhouse experiment that Naeem and collaborators had performed earlier.

In total, these studies provide strong evidence that communities with greater diversity are more stable and suggest that individual species in such communities may be less stable. Theory, experiment, and observation are in general agreement, but this topic merits additional exploration.

Conclusions

The research performed to date illustrates that a variety of different ecosystem processes are impacted by the number and kinds of species living in the ecosystem. This work illustrates that species differ in traits that influence ecosystem functioning and suggests that ecosystem processes depend on the range in those traits represented in the ecosystem. However, there are, as yet, no clear demonstrations of the specific traits that are relevant to particular ecosystem processes and no simple ways to directly measure functional diversity. Rather, correlates of functional diversity, such as species richness or functional group richness, remain the best, albeit indirect, way to measure functional diversity.

Glossary

Available Of a scientific name of an organism, one that must be taken into account when deciding the correct (q.v.) name to be used for it.

Binomen A binominal or binary name of a species, consisting of the name of the genus in which it is placed followed by a word peculiar to that species.

Code In nomenclature, one of the sets of internationally agreed rules governing the scientific names of organisms.

Conserved Of a scientific name, one that the appropriate international body has decided should continue to be used for an organism in cases where a strict application of the Code (q.v.) would mean it had to be replaced.

Correct Of a scientific name of an organism, one that conforms to the appropriate international Code (q.v.) for the position in which it is placed.

Priority Of a scientific name, its date of valid publication; the first published name is generally the one to be used, subject to the provisions of the pertinent Code (q.v.).

Synonym One of two or more scientific names applied to the same organism.

Taxon A taxonomic entity or group of any rank, including all subordinatedly ranked taxa placed within it.

Type Of an organism, the specimen, culture, or other element on which a scientific name of an organism is based and that fixes its application; the name-bearing type.

Valid Of a scientific name, one that conforms to the conditions of valid publication proscribed in the relevant Code (q.v.).

Introduction

Systems of nomenclature are the procedures developed to provide the scientific names of organisms. This article concentrates on the consensual systems that operate in different groups of organisms through a series of published, internationally adopted Codes. It also discusses why scientific names change, the procedures involved in the naming of newly discovered species, and provides hints for ascertaining the current name of an organism. The article is concerned only with the nomenclature of organisms, that is, bionomenclature, and not with systems developed for naming parts of the genome, parts of the organisms, or communities of plants or animals.

Purpose

The purpose of systems of nomenclature is to provide an unambiguous mechanism that enables biologists and all others who work with organisms to communicate by a scientific name so as to avoid misunderstandings and confusion. Scientific names are Latinized (though not necessarily based on Latin words) and given to organisms of all kinds, whether living or fossil, and are in effect a universal currency – the means of connecting together and accessing the accumulated knowledge of any particular organism. The same species may have different common or colloquial names in a variety of current languages, but can bear only a single correct scientific name.

Nomenclature is not the same as taxonomy, although the two are often confused. Taxonomy, a component of systematics (or biosystematics), is concerned with drawing up

classifications, with deciding, for example, to what genus a species belongs, whether two species are really the same, or whether one species should be divided into two. Nomenclature is the process of determining what scientific names, in effect labels, should be applied to the units that taxonomic research considers to merit independent names. Nomenclature is subservient to taxonomy; it is not science itself, but the method by which scientific results are made available for general use.

The application of naming systems is complicated because new research may show that a particular taxonomy does not reflect the evolutionary (i.e., phylogenetic) relationships of the organisms concerned. Further, the same species may have been described more than once by different scientists, and placed in a number of genera according to different taxonomic opinions. The net result is that there are many more scientific names than known species in the scientific literature. The full extent of the problem is unclear, but in the case of non-fossil groups traditionally viewed as “botanical” (i.e., algae, fungi, and plants) there are approximately 1.7 million species names available for 406 000 accepted species. It is the challenge of nomenclatural systems to provide clear procedures of how to handle a morass of names that may have been applied over the centuries to the same organism.

Origins

From the earliest times, humans needed to communicate taxonomic information: to tell each other which animals or plants are a threat, which can be eaten, which make tools or dyes, or which can help cure particular ailments. Indigenous peoples today confront the same problems, and often have

sophisticated naming systems for organisms of importance to them; interestingly, the species concepts they employ are often not too divergent from those a taxonomist would adopt. The basic need to name organisms was recognized even in The Bible, where one of Adam's first tasks was to name the animals, and there are now indications that one area of the human brain is devoted to discriminating living organisms.

Problems arose when different peoples needed to communicate with each other, and even the use of Latin as a language of scholars failed to solve the problem. Descriptive phrases written in Latin came to be used, but these polynomials were cumbersome and difficult to remember. For instance, the tea plant was referred to as *Evonymus affinis arbor orientalis nucifera, flore roseo* by Leonard Plukenet in 1696. By the early eighteenth century the situation was becoming impossible, and it was Carl Linnaeus (1707–1778) in Sweden who developed a pragmatic solution that remains the basis of our current nomenclatural systems. Linnaeus at first followed several earlier authors in grouping his species into categories that had a single name, in effect a genus. However, in 1737 he started to use a single second name to denote the species in the indexes in his books. This shorthand practice entered the main texts of some of the works he was associated with in 1751, and he then went on to produce accounts of all organisms known throughout the world using this approach; the species names were printed in the margins offset from the main text. Instead of Plukenet's polynomial for the tea plant, Linnaeus simply used the binominal, or binary name, *Thea sinensis*. Such a radical change was not well received by all of his contemporaries, who regarded him as autocratic, but his *Species Plantarum* (1753) and *Systerna Naturae* (10th edition, 1758) were destined to become designated as the starting points of the modern nomenclature of most forms of life.

Hierarchical Systems

Nomenclatural systems are based on a series of ranks. Each species is referred to a genus, a genus to a family, a family to an order, and so on. The principal ranks available are, in descending order: domain, kingdom, phylum (or division), order, class, family, tribe, genus, section, species, and subspecies. Additional ranks can be intercalated using the prefixes super- and sub- (e.g., superfamily above family, subfamily below family). In practice, all the possible ranks are rarely used in any particular case.

Though the number of available ranks may seem large, the current system cannot adequately satisfy those who wish to recognize each branching point in a cladogram, and proposals for a modified rankless system has been made in the Phylo-Code (see The PhyloCode), which is independent of the organismal Codes and does not at present deal with species names.

Some of the ranks above genus have standardized suffixes that enable them to be recognized (Table 1), but there are exceptions for some well-known names approved by the relevant international nomenclatural bodies; for example, the grass family *Gramineae* (not *Graminaceae*). There are no rank-indicating endings used above phylum in botany, none over

Table 1 Hierarchical ranks and suffixes indicating them

order in bacteriology, nor any over superfamily in zoology – although traditions have in some cases developed.

The names of families are based on the name of an included genus, such as *Nostocaceae* on the genus *Nostoc*. Order names are also based on generic names in algae, fungi, and plants, but not necessarily so in animals, where the characters of the order tend to be employed. At ranks above order, there are no strict rules, but the names usually reflect some key distinguishing feature.

The only rank below species that is formally recognized in bacteriology and zoology is that of subspecies. In zoology the subspecies name follows that of the species without any indication of rank to form a trinomial, for example, *Mus musculus domesticus*, whereas under the other main Codes the rank is made clear by the insertion of subsp. or ssp., as in *Silene vulgaris* ssp. *maritima*. The insertion of a rank term in those cases is essential to make clear which is referred to: "var." denotes variety and "f." denotes a form. In botany, additional terms are used in particular groups, most notably "cultivar" ("cv.") for stable propagated cultivated plants and "special form" ("f. sp.") for pathogenic fungi attacking different host plants that cannot be separated morphologically. However, with the advent of molecular techniques the use of special form is becoming obsolete as species concepts become better understood.

Scientific names in the rank of genus and above always start with a capital letter. Generic, specific, and formal ranks below species (see Table 1) are always printed in italic script. The practice at other ranks varies, and is a matter of editorial

style as this is not ruled on in any of the existing Codes. Although in zoology it is not usual to italicize any other ranks, the scientific names of algae, fungi, and plants at all ranks are italicized in the most recent Code (see Codes of Nomenclature), and this practice is increasingly being adopted in botanical and mycological publications as well as being advocated in the interdisciplinary BioCode (see The Draft BioCode).

Principles

All Codes share a common objective: the scientific name of an organism must be unique and stable in a particular classification (i.e., a taxonomy). Nomenclature can be thought of as a tool used when it is necessary to decide on the name to apply to a particular organism or other hierarchical rank; it must not constrain the science of taxonomy. To achieve this objective, each name needs to be formally introduced by agreed upon procedures. There must also be a means of ensuring that the application of every name is fixed so that it can always be applied unambiguously. In cases where more than one name has been proposed for the same organism, the basis on which to make a choice must also be unambiguous so that different researchers will be led to apply the same name where they have identical taxonomies.

Names of genera and species can be formed from any source, but are treated as if they were Latin. Ideally they should be informative, giving some clue to their features, but they are often based on the names of their discoverers or the places where they were found. However, this is not always the case; they can even be derived from acronyms or be anagrams. Today, the etymology of newly coined names is generally expounded when they are first introduced.

A consequence of treating species names as if Latin is that their endings must agree with the gender of the genus in which they are placed. The ending of the name of the same species may thus change if it is transferred from a genus that has a female gender to one that is male.

The name of the person (or persons) who first introduced a scientific name is often indicated after the name itself, sometimes with the date of the publication. This device, referred to as an author citation, is essentially a much abbreviated reference to a particular publication, and although often interpreted as recognizing the contribution of that person, it can also be viewed as attributing blame to the person who burdened the scientific literature with it – especially as so many names prove to be unnecessarily coined for species that are later found to have previously been described. It is much easier and takes less time to describe an organism as new to science than to determine if it has already been named. If an author's name appears without brackets, it was introduced just like that. If the name is in brackets, the name was originally in another genus or rank.

The citation *Simulium albellum* Rubtsov tells us that Rubtsov published that species name in the genus *Simulium*; *Obuchovia albella* (Rubtsov) makes clear that Rubtsov introduced the species name of this fly but did not refer it to the genus *Obuchovia*. In bacteriology and botany, the name of the person making the change in generic placement or rank

follows any name placed in brackets. For example, the citation of the Fool's Watercress, *Apium nodiflorum* (L.) Lagasca, indicates that L. (Linnaeus) coined the name (actually as *Simulium nodiflorum* L.) but that Lagasca first placed it in the genus *Apium*. Names such as *Simulium albellum* and *Sium. nodiflorum*, which give the name being used in a different rank or combined in other genera, are termed "basionyms;" names using such basionyms in a different rank or position are "combinations."

The abbreviation of the names of authors, such as L. for Linnaeus in this case, is commonplace, especially in algae, fungi, and plants where an internationally recognized list of abbreviations to be used for particular authors was issued in 1992; initials are inserted where there is more than one author with the same surname. An ex will sometimes appear inserted between the names of two authors; this means that the one before it first used the name but did not meet some requirements of validity or availability (see the following), whereas the second author did. However, there are instances in zoology where the role of the authors as given in the citation is reversed, with the first being the one first correctly publishing the name.

The way in which names are published is also specified in the different Codes. These relate to the publication itself (effective publication), which must be available to the scientific community, and the matter that must be associated with a name when it is introduced (valid publication), for example, a description and details of the material on which the name was based (the name-bearing type, discussed next). Only if the specified criteria are met does a name formally enter the body of scientific literature and become available for use. From 1st January 2012, electronic-alone publication is considered effective for algae, fungi, and plants provided the journal has an ISSN number, and proposals to change this are under active consideration for inclusion in the next editions of the zoological Code. The reluctance to immediately accept electronic-only publication is due to taxonomists being concerned about the accessibility of electronic-only resources for centuries to come as technologies are evolving so rapidly.

The name-bearing type irrevocably now fixes the application of a name. This is usually a single specimen permanently preserved in a museum or other public institution, but in some cases it can also be a microscopic preparation, drawing, photograph, or microbial culture. The original material used and specified by the author is a holotype; a lectotype is material from the original author's collection selected to act as the name-bearing type by a later researcher; a neotype is a later collection chosen to serve as the name-bearing type where no original material remains. Types are not necessarily representative of the range of a species or subspecies, but are simply a nomenclatural device to unambiguously fix the application of names. They are consequently a very important reference point in biological communication and merit careful preservation and handling as they will remain of relevance for centuries.

A key feature in all Codes is the priority by date accorded to the names to be used for an organism. The name to be adopted is generally the first published in the same rank or group of ranks, depending on the Code.

Surprisingly, with the exception of bacteriology, mycology, and some groups of cultivated plants, there is no obligation

on a person introducing a new scientific name to register it with some international authority. Proposals to introduce such a system for botanical groups were accepted in principle in 1993 and were to be introduced for the year 2000, but the 1999 International Botanical Congress reversed that decision. Proposals to make this mandatory for fungi were, however, adopted at the Melbourne Congress in 2011 and are required from 1st January 2013. The names of fungi after that date must be registered to be considered validly published; registration in MycoBank has been tried and tested was already being enforced by the leading mycological journals and information on approximately 80% of fungal names proposed each year was already being deposited voluntarily.

Conscious that the application of a rigid system of rules could lead to unwelcome and confusing name changes, the Codes have developed a variety of mechanisms for overcoming this. These involve cases being published for open comment and consideration by international committees who debate them and express an opinion or recommend a particular course of action. Names can be conserved against ones that otherwise would have to be used, or rejected, in which event they cannot be taken up. In some instances, whole publications can be suppressed from usage.

An Approved List of names is published in bacteriology. Virus Taxonomy approaches this, and there is an Official Lists and Indices of Names and Works in Zoology. There is no exact equivalent for algae, fungi, and plants, although some of the appendices of protected and rejected names to that Code approach them, at least in part and approval for Lists to be developed for fungi was granted at the Melbourne Congress in 2011. Proposals to develop protected lists of botanical Names in Current Use were debated, but finally rejected by the International Botanical Congress in 1993. However, Adopted Lists of Names are a feature of the Draft BioCode (see The Draft BioCode), currently under discussion.

Names other than the one to be used that have been proposed for the same biological unit are termed “synonyms.” These can be of two types: “homotypic” (“objective” or “nomenclatural” synonyms) and “hetero-typic” (“subjective” or “taxonomic”). Homotypic synonyms are based on the same name-bearing type, whereas heterotypic ones are based on different name-bearing types. Thus, homotypic synonyms are irrevocably linked, whereas heterotypic synonyms are dependent on the opinions of taxonomists on the placement of the different name-bearing types.

Codes of Nomenclature

The five current organism-related Codes differ in their detailed provisions. All are complex documents approved by particular internationally mandated bodies. Each has its own history of development and special characteristics. Some of their distinctive features, differences, and procedures are summarized here.

Algae, Fungi, and Plants

A single Code (McNeill *et al.*, 2012) covers algae, fungi, and plants; the organisms traditionally studied by botanists even

though many are no longer classified in the plant kingdom (*Plantae*). It consequently embraces cyanobacteria (*Bacteria*), fungi (*Fungi*), slime-molds (*Protozoa*), and various algal groups (*Chromista*, *Heterokonta*, or *Straminipila*). The name of this Code was changed from the International Code of Botanical Nomenclature in July 2011 to reflect the disparate organisms it covers.

The nomenclature of these groups is considered as starting from the publication of Linnaeus' *Species Plantarum* in 1753, but the first internationally agreed Code dates from the *Lois de La Nomenclature Botanique* prepared by Alphonse de Candolle in 1867 and adopted by the International Botanical Congress in Paris that year. Later starting dates, all linked to particular major publications by authors other than Linnaeus are used for some groups, notably mosses (1801), certain groups of algae (1848–1900), and fossils (1820). Fungal names were formerly dated from 1801 or 1821, depending on the group, but that practice was discontinued in 1981. Names of fungi accepted in the previous starting point works by Christian Persoon (1801) and Elias Fries (1821–1832) remain sanctioned for continued use even if earlier competing names exist. Traditionally, the distribution of hard-copy publications, i.e. books or journals, was required for effective publication under the Code. However, this situation changed. From 1st January 2012, electronic publications are accepted as a means of effective publication, provided that certain criteria are met. The work must have an ISBN or ISSN number, as appropriate, and be in its final form and archived. Articles in journals that are made available online and in an unalterable form prior to distribution of printed copies are now considered effectively published and date from the date on which the online version was published.

In addition to the insertion of terms to denote ranks below species and differences in the practice of how describing authors are cited, several features of this Code are unique to it. New scientific names published after 1935 and before 1st January 2012 must, with a few special exceptions, have a description or diagnosis (i.e., a statement of how the organism differs from others) in Latin. However, on or after 1st January 2012, the validating diagnosis or description must be in either English or Latin.

This Code recognizes the priority of names only within the particular rank under consideration. This means, for example, that even if a plant was recognized as a subspecies or variety long before a species name was coined, the species name is nevertheless the one to be used. In addition, this Code rules as illegitimate names that have been introduced unnecessarily when another should have been adopted by the author, for instance, by placing an earlier validly published name as a synonym when it was introduced. Also illegitimate are names spelled in either exactly the same way or are so similar in spelling that they are likely to be confused; these names are termed “homonyms”, and only the oldest is generally available for use. For example, *Erica hibernica* (Hook and Arnott) Syme 1866 is illegitimate and to be rejected because of the existence of *Eri. hibernica* Utinet 1839, which represents a different species and is based on a separate name-bearing type. That Syme's name was based on *Eri. mediterranea* var. *hibernica* Hook and Arnott 1835 does not affect the situation, as that name has priority from 1835 only in the rank of variety and not of species.

Name-bearing types have had to be designated when describing new species and infraspecific taxa in this Code since 1958, and from 1990 the institution where they are preserved must also be cited. Living type material is not permitted, but dating from 1993 freeze-dried (lyophilized) material or specimens of algae or fungi preserved in liquid nitrogen are acceptable provided they are maintained in a metabolically inactive state; resuscitated cultures from such material are then referred to as ex-holotype, ex-isotype, etc.

This Code has special provisions for hybrids, fungi and fossils, which are considered separately below (*see* Special Cases). Appendices listing conserved and rejected names, and suppressed publications form a part of the Code, but at the International Botanical Congress in Melbourne in 2011, it was decided that the appendices need not be printed in the Code itself but could be published separately. The provisions of this Code are debated at each 6-yearly International Botanical Congress, after which a new edition of the Code is issued. Any changes proposed have to be published, something generally done in the journal *Taxon*, are balloted on first by mail (by individual members of the International Association for Plant Taxonomy), and then at the Nomenclature Section meeting of the Congress itself, where a 60% majority is normally required to effect any change. The Congress establishes a series of permanent Committees that are charged with considering and making recommendations on proposals to reject or conserve names in different groups; those are also generally published in *Taxon* and are ratified by the subsequent Congress.

New proposals to be placed before the next Congress in 2011 include ones to permit electronic-only publication under particular circumstances, a move from mandatory Latin diagnoses (*see* above), the transfer of decision making in relation to matters concerning fungi to International Mycological Congresses (now organized every 4 years under the auspices of the International Mycological Association), and to require the prior deposit of key nomenclatural information in a recognized online repository (currently MycoBank) for the valid publication of fungal names.

Cultivated Plants

The cultivated plant Code (Brickell *et al.*, 2009) split from the International Code of Botanical Nomenclature in 1952. It is primarily concerned with the naming of cultivated varieties or cultivars, which are propagated horticulturally by any method that retains their characteristics in a stable way. It is now complementary to the International Code of Nomenclature for algae, fungi, and plants, and does not compete with it, as species names and those in other formal recognized ranks of cultivated plants remain subject to the same rules as wild plants.

Cultivar names, with a few established exceptions, are not Latinized and since 1958 have been required to be in a modern language; they are placed within single quotation marks and never printed in italic type, for example, *Rubus nitidoides* "Merton Early," in which "Merton Early" is the cultivar name and *R. nitidoides* is the botanical species name. The abbreviation cv. can be inserted before the cultivar name but is generally omitted. It is also not uncommon for the species

epithet to be dropped as well in garden catalogs (e.g., *Rubus* "Merton Early"). Similar cultivars can be grouped into cultivar-groups; this is achieved by placing a group name in brackets before the cultivar name and without quotation marks, for instance, *Rosa* (Hybrid Tea Group) "Richmond"; if the particular cultivar is not being cited, the brackets are omitted (e.g., *Rosa* Hybrid Tea Group).

In the case of orchids, groupings of cultivars based on parentage are called grexes (or more correctly greges); their application follows separate provisions in The Handbook of Orchid Nomenclature and Registration (1993).

Graft-chimeras, in which living tissues of two species are made to grow together by grafting, can also be named under this Code. These are indicated by the use of a + sign in a manner equivalent to the use of × in the names of hybrids (*see* Hybrids). The form *Crataegus monogyna* + *Mespilus germanica*, for example, indicates a graft with tissues of both of those plants. A Latinized name can be used instead provided that the + sign is retained and the resultant name is not identical to a name of a hybrid; in this example, the name + *Crataegomespilus dardarii* has been coined. Cultivar names can be added after the name of the graft-chimera.

Names of cultivars have to be established through publication and not by garden labels or confidential trade lists. There must also be a reference point for their application, a standard dried specimen preserved in a herbarium, or in some cases an illustration. There is then a system of 72 International Cultivar Registration Authorities (ICRAs), each dealing with particular groups of cultivated plants, that register newly proposed names and make lists of these available. In addition, there are also national Statutory Plant Registration Authorities recognized by the International Union for the Protection of New Varieties of Plants (IPOV).

The cultivated plant Code operates under the auspices of the International Commission for the Nomenclature of Cultivated Plants.

Prokaryotes

The Bacteriological Code (Lapage *et al.*, 1992) arose as an offshoot of the International Code of Botanical Nomenclature in 1939, in large part due to the need to accept living cultures as name-bearing types. In consequence, there are many similarities between the two Codes, although they have diverged in some respects. Although the printed version is labeled Bacteriology, it covers both *Archaea* and *Bacteria*, and so is being increasingly referred to as the Prokaryote Code under which name the next hard-copy version will appear. The most striking feature of this Code, and a response to the problem of the large numbers of bacterial names of uncertain application, a start date of 1980 was established and linked to an Approved List of Bacterial Names; names published prior to 1980 and not on the list do not exist for nomenclatural purposes, that is, they are not treated as validly published and so are no longer available for use. At a stroke, the number of species names that had to be considered by bacteriologists was reduced from approximately 32 000 to 3000.

New names of bacteria now have to be published in or be registered by the *International Journal of Systematic and*

Evolutionary Microbiology, and will then be added to the next edition of the Approved List; a continuously updated online system is available through the Internet.

The realization that many bacteria, and especially archaea, can be identified on the basis of molecular sequence data but not grown in culture is challenging the requirement for living cultures to be designated as name-bearing types. In addition, many cyanobacteria described under the botanical Code have name-bearing types that are dried specimens or microscopic preparations. Prokaryotic organisms that cannot yet be fully described and have designated type cultures can, however, be given a name but in a status termed “candidatus” – candidates for species.

Although the only rank below species to be formally recognized in the prokaryote Code is that of subspecies, “pathovar” (“pv.”) is employed for plant pathogens essentially distinguished only by the ability to cause diseases in particular plants; for instance, *Xanthomonas campestris* pv. *durantae* (on *Duranta repens*) and pv. *erythrinae* (on *Erythrina indica*). Regulations regarding pathovar names and lists of those proposed are prepared by a committee of the International Society for Plant Pathology. Strain or serological type names or numbers are commonly used in bacteria of medical importance, but these have no standing under the Code.

The prokaryote Code operates under the aegis of the International Committee on Prokaryote Systematics (ICPS), which is a part of the International Union of Microbiological Societies (IUMS). The Committee has a Judicial Commission, which reports back to the International Committee, and has wide powers to propose changes to the Code, which do, however, have to be subsequently ratified by IUMS congresses.

Viruses

The naming of viruses was controversial for many years. Two different systems were operating in parallel: a traditional system recognizing families, genera, and species with Latinized names, and a divergent one employing the categories of group, subgroup, and type (or virus) and in a modern language. The former held sway among those working with viruses in animals, and the latter among plant pathologists. In the case of plant viruses, a scientific name indicative of the structure of the virus was generally preceded by an indication of the host and (or) the symptoms caused; for instance, the Desmodium mosaic potyvirus and the Desmodium yellow mottle potyvirus.

The situation started to change rapidly in 1991 when the International Committee on the Taxonomy of Viruses, which operates within the International Union of Microbiological Societies, decided to use the traditional approach with Latinized family and genus names, but to retain English names for species. New guidelines were drawn up and adopted by the International Congress of Virology in 1993, and the latest revision of these was published in 2011 (King *et al.*, 2011). Proposals to modify the rules relating to virus names may be aired in *Archives of Virology*, which also includes reports of meetings of the Committee and periodically a survey of all accepted virus taxa.

Virus names can be recognized by their endings even down to the rank of genus; generic names have the suffix *-virus*

(see Table 1), whereas the species names remain in English. For example, the genus *Ipomovirus* has as its type species Sweet potato mild mottle virus, whereas that of the genus *Roseolovirus* is Human herpesvirus 6.

Zoological Organisms
